GUTTA SERENA. A term said to have been first applied by Actuarius to amaurosis, or the species of blindness arising from a morbid state of the retina or optic nerve.—(See *Amaurosis.*)

In the present place I mean first briefly to advert to a case which the late Mr. Ware has described as combined with a particular kind of ophthalmy, that occasions excruciating pain, and requires peculiar treatment. One example of this kind was greatly relieved by a puncture made through the tunica sclerotica into the ball of the eye with a grooved needle, somewhat larger than a common-sized couching needle, nearly in the part where this instrument is introduced in the operation of depressing the cataract. Through the groove of the instrument a watery fluid immediately issued, which was not unlike that which Mr. Ware several times found after death effused between the choroid coat and retina in cases of gutta serena. After the pain of the operation had ceased, the patient became quite easy, and the inflammation soon subsided. Mr. Ware afterward performed a similar operation in a considerable number of resembling instances, and in several of them the proceeding was attended with almost immediate good effect.—(See *Ware on the Operation of largely puncturing the Capsule of the Crystalline Humour, &c. and on the Gutta Serena, accompanied with Pain and Inflammation*, 1812.)

Under the head of gutta serena I promised to notice Beer's opinions concerning amaurotic remedies, which he divides into two classes, viz. *general* or *internal* means, and *local* or *external*. Sometimes only the first are requisite; more rarely only the second; but frequently both together.

Among the internal remedies are emetics, which may be useful in two ways, either as real evacuants, or as nauseating means. It was Beer's opinion that for the purpose of exciting actual vomiting they should be exhibited only when the stomach is foul, and no considerable plethora exists; and he deems them improper whenever any great determination of blood to the head and eyes prevails, or any increased velocity of the circulation. Should the surgeon find it necessary to employ emetic medicines, simply as alteratives, he must consider well whether the digestive organs will bear their great and long-continued operation.—(*Lehre von den Augenkr. b.* 2, *p.* 463.) Notwithstanding the favourable accounts given by Schmucker, Richter, and Scarpa of the good effects of emetics in many cases of amaurosis abroad, this treatment has had but little success in England. Mr. Travers even declares that he does not recollect an instance of decided benefit from the emetic practice, although he has fairly tried it. "The cases of gastric disorder, to which it is especially appli

cable are most benefited by a long-continued course of the blue pill, with gentle saline purgatives and tonic bitters."—(*Synopsis of Diseases of the Eye, p.* 304.) Mr. Lawrence also states in his lectures, that in this country the treatment of amaurosis by emetics is not attended with the success that has resulted from it abroad.

When the bowels are loaded, and there is frequent determination of blood to the head and eyes, and an accelerated circulation, and, particularly, if after these effects the sight is always manifestly worse, brisk purgatives may be prescribed. When, however, constipation has prevailed for a long time, drastic purgatives should not be exhibited before one or two loose motions have been procured with laxative clysters. Gentle aperients are more particularly indicated when the patient does not have a stool daily, and the evacuation is never made with ease nor without considerable straining; when he often passes two or three days without any evacuation at all, circumstances sure to be followed by repeated determination of blood to the head and eyes, and other ill consequences, which, according to Beer, have a very prejudicial effect on amaurosis.

Beer is of opinion that diaphoretics should be employed with great caution, because they are apt to bring on violent determinations of blood and an accelerated state of the circulation; and they can only be employed with judgment and a hope of benefit when there are good grounds for believing that a previous stoppage of the cutaneous functions has had a real share in producing or keeping up the blindness. They are still more strongly indicated when the cessation of those functions is, in some measure, evinced by the dry state of the integuments, wandering pains between the skin and muscles, and considerable melioration of the eyesight after the breaking out of any accidental perspiration.—(*B.* 2, *p.* 465.)

Professor Beer thinks that in amaurosis medicines for promoting the menstrual discharge are too often employed on empirical principles, to the serious detriment of the patient, the cessation of this discharge being mostly regarded as the cause of the amaurosis, while, in reality, it is very seldom really so, both affections being dependent upon one and the same cause. Hence much circumspection and the closest investigation are necessary to trace the connexion between these morbid effects, and to ascertain when such medicines can be given without risk.

Still greater mischief results from the treatment of amaurotic children with anthelmintics; nay, Beer assures us, that he has seen numerous amaurotic boys and girls thus wrongly treated, who had not the slightest symptoms of worms. However, when amaurosis is unattended with any leading indications, anthelmintics may be tried, for they are less injurious to the eyes than many other medicines, though, as they consist of drastic purgative means, they must soon occasion great debility.

According to Beer, when there is good ground for suspecting the patient to be suffering from the effects of syphilis, mercurials may be given with great prospect of benefit. Also, when no suspicion of this kind can be entertained, but amaurosis is accompanied with infarction of the abdominal viscera, especially chronic disease of the liver, or serious chronic swellings and indurations of the glands, a periodical headache of no determinate character in other respects, and aggravation of the blindness after every such attack, mercurial preparations, as Beer can assert from manifold observation, are productive of the best effects upon the disease of the eyes. Yet, says he, under these circumstances mercury should never be exhibited where the individuals are of a debilitated scorbutic diathesis or subject to bleedings, and more particularly where there is the least mark of a dissolution of the vitreous humour.—(*Lehre von den Augenkr. b.* 2, *p.* 466.) Upon the whole, from what I am able to learn of the practice in London, mercury, preceded by antiphlogistic remedies, is more extensively and successfully used as a remedy for amaurosis than any other medicine in the whole pharmacopœia. "When the amaurosis is recent and sudden (says Mr. Travers), and either the signs of an obscure inflammation are present, or only the amplitude and inactivity of the pupil correspond to the patient's history—mercury should be introduced with all convenient rapidity into the system, I mean, so as to ruffle it in the least possible degree. No advantage is obtained by salivation; on the contrary, I think it hurtful: when mercury is beneficial, its efficacy is perceived as soon as the mouth is sore."—(*Synopsis of the Diseases of the Eye, p.* 305.)

Antinervous medicines have at all times ranked very high on empirical principles, as means for the cure of amaurosis; but how often is this disease not simply a nervous affection? Beer divides the medicines of this sort, employed in cases of amaurosis, into three classes, namely, *antiparalytic, antispasmodic*, and *tonic*. To the *first class* belong arnica, naphtha, camphor, millepedes, sulphur auratum, antimonii, liquor ammoniæ lavendulatus, pulsatilla, black hellebore, and phosphorus. These medicines can be safely given to amaurotic patients when an evident general nervous debility and morbid irritability prevail, without any other particular appearances of disease, and especially when, at the same time, there are genuine paralytic appearances in the eye itself, or in the parts immediately surrounding it, or not very far from it. Among the *antispasmodic* remedies, particularly when used on empirical principles, Beer has found the most efficacious to be valerian, liquor ammoniæ carbonatis, asafœtida, opium, hyoscyamus, castoreum, musk, flores zinci, and extract of chamomile. *Tonic* nervous remedies (says Beer) are to be used with more caution; for bitter medicines, when injudiciously prescribed for nervous, debilitated individuals, rather promote the formation of amaurosis. When calamus aromaticus is in question, care must be taken that there be no tendency to pectoral complaints, which this medicine is too apt to bring on in weak subjects, in which event the sight is always very much impaired by it. In costive habits, bark is likewise apt to render the blindness worse. And according to the same experienced oculist, it is necessary to be very circumspect with steel medicines, empirically prescribed, as they frequently occasion determinations of blood to the head and eyes, and quicken the circulation, whereby every remnant of vision may be abolished. Steel medicines do the greatest and quickest injury to amaurotic eyes, when combined with narcotics. Above all things, it is generally prudent, in cases of amaurosis, carefully to abstain from all the stronger and long-operating nervous medicines, whenever plethora, determinations of blood, and tendency to inflammation exist.—(*Lehre von den Augenkr. b.* 2, *p.* 467.) In this country, I do not believe that antinervous and antispasmodic medicines have obtained credit for their efficacy in this disease. Thus, Mr. Travers states, that he has never known any real benefit derived from camphor, asafœtida, valerian, &c., though he has seen much good derived from tonics, the mineral acids, bark, steel, and arsenic, after a due regulation of the digestive functions.—(*Synopsis, &c. p.* 304.) In arnica montana, aconite, euphrasia, and stimulants in general, he has no confidence.

Local or *external* medicines for amaurosis are divided by Beer into two classes, namely, into those which are applied to parts more or less distant from the eyes, and having some sympathetic connexion with these organs, and into others which are usually put upon the eye itself.

In the first class, bleeding has obtained high repute, either by venesection in the common way, the application of leeches to the pudenda, the arms, behind the ears, or upon the temple; cupping the back, or by opening the temporal artery or jugular vein. Bleeding is indicated when manifest plethora, a determination of blood to the head and eyes, or an accelerated circulation is combined with a considerable decrease of vision; when the menses are nearly or quite suppressed in plethoric subjects, a manifest determination of blood to the parts of generation prevails; or the same thing occurs in hemorrhoidal patients.—(*Beer, Lehre, &c. p.* 469.)

According to Mr. Travers, all the cases of direct debility and proper paralysis of the optic nerve are aggravated by loss of blood.—(*Synopsis, &c. p.* 303.)

Professor Beer gives his testimony also in favour of the efficacy of such applications as produce a counter-irritation, not merely as rubefacients, but as means occasioning an evacuation of lymph; such are blisters, sinapisms laid on the back or calves of the legs, vesication by means of the bark of mezereon, issues, and setons. These means are proper when the blindness is attended with continual but wandering pains in the aponeurotic covering of the head, or in the vicinity of the eye, with a whizzing noise and irritating pain in the ear, or with the suppression of a purulent discharge from the meatus auditorius. In such cases, however, there must be no particular plethora, still less any determination of blood to the head and eyes. Here

should also be mentioned friction with antimonial ointment, which is especially indicated where there is reason to believe that the amaurosis has been preceded, and partly produced, by a long interruption of the cutaneous secretion.

Beer says, that aperient clysters are attended with the most decided good effects in that amaurotic weakness of sight which sometimes occurs towards the end of pregnancy, and is combined with obstinate constipation, continual headache, evident determination of blood to the head and eyes, and such an inflammatory diathesis as cannot be mistaken. On the other hand, the employment of clysters as anodyne remedies, not as evacuants, is principally useful in hypochondriacal and hysterical amaurotic patients, when they are troubled with much general cramp and spasms in the abdomen.—(*Vol. cit. p.* 470.)

According to the statements of the same writer, baths, whether warm or cold, adapted for the whole body or in the form of a slipper-bath, a pediluvium or affusion, have hitherto not proved very efficacious remedies for amaurosis; and this, whether they consist of simple water, or aromatic decoctions, or of waters impregnated with sulphur or iron. The reason why baths in general are less frequently employed as empirical remedies in cases of amaurosis, and why they are still more rarely successful, may be because in the very cases of amaurosis in which baths of various kinds are clearly indicated, the greatest attention must be paid to the patient's constitution, to the state of the skin especially, and to the temperature of the fluid employed; for, in a healthy subject, too warm a bath may, under certain circumstances (as, for instance, when there is plethora), of itself occasion a serious amaurotic amblyopia; and therefore, under similar circumstances, must be likely to increase any present amaurotic weakness of sight into complete blindness. In general, warm or slipper-baths must be employed as empirical remedies in amaurosis only when the regular action of the skin is disturbed, without febrile symptoms, when the affection of the eyes has been preceded by the sudden stoppage of a profuse perspiration, or some cutaneous efflorescence is coexistent with the amaurosis. On the contrary, pediluvia with salt, mustard, &c. are chiefly proper when amaurosis is accompanied with a determination of blood to the head and eyes, or any local inflammations, after which the eyesight is always found to be worse. In cases of amaurosis, affusion can be seldom used empirically, and only under those circumstances where modern experience has proved the shower-bath to be allowable. Cold bathing generally agrees badly with an amaurotic patient, and when his skin is extremely sensible, when wandering pains are felt between the integuments and muscles, or there is a tendency to erysipelatous inflammation, the power of vision evidently declines after every trial of the plan. But, according to Beer, mineral waters impregnated with iron, in the form either of a bath for one half or for the whole of the body, generally produce, under these circumstances, the most favourable effects upon the skin, and, through the medium of it, upon the diseased eye. The case, however, is to be excepted where flying rheumatic, and perhaps gouty, pains constantly tease the patient, unaccompanied with fever, and where bathing of the whole body in sulphurous mineral water should be preferred.—(*Lehre von den Augenkr. b.* 2, *p.* 471, 472.)

If we are to believe Beer, the empirical employment of applications which have the effect of increasing the secretion of mucus is very seldom proper, such as irritating gargles, the smoking of tobacco, and sternutatory powders; for these means can only be adopted with any prospect of benefit when amaurosis is accompanied with plethora, a sense of spasm and weight about the frontal sinuses, an incessant, obtuse heaviness at the bridge of the nose, and unusual dryness of the nostril, in an individual who has frequently suffered catarrhal complaints, but some time previously to the origin of the amaurotic symptoms has continued nearly or quite free from colds; and when the patient has no tendency to plethora, determination of blood to the head and eyes, and acceleration of the circulation.—(*Vol. cit. p.* 473.)

The application of sternutative powders to the nostrils is, perhaps, to be regarded as a mode of treatment established on empirical principles, unless we can place confidence in the statement of Schmucker, Richter, and Beer, that an unusual dryness of the mucous membrane of the nose, following tedious and severe catarrhs, may have the effect of inducing amaurosis. The snuff employed by Schmucker is thus composed: ℞. Mercur. viv. ʒ i. Sacchar. alb. ʒ iij. Lill. alb. rad. valerian ā ā ʒ j Misce.

The late Mr. Ware imputed considerable efficacy to electricity and a mercurial snuff in cases of gutta serena. The snuff was compounded of ten grains of turbith mineral (*hydrargyrus sulphuratus*), well mixed with about a drachm of the pulvis sternutatorius, glycirrhiza, or common sugar. A small pinch of this snuff taken up the nose is found to stimulate it very considerably; sometimes exciting sneezing, but in general producing a very large discharge of mucus.—(See *Chir. Obs. relative to the Eye, vol.* 1.)

Among the remedies which are intended to be applied directly to the eye and its surrounding parts, local bleeding merits the first rank. The extraction of blood by means of leeches, or by cupping the temples, is the only mode in which the practice can here be executed. The method, however, is only proper when manifest turgescence of the vessels of the conjunctiva and sclerotica is combined with a feeling of constant pressure about the eye, a sense of fulness and tension in the ball, and evident plethora, without any local inflammation or increase in the velocity of the circulation.

Experience proves also, says Beer, that the empirical application of rubefacients, or drawing-plasters, to the temples or eyebrows is fraught with not less efficacy when all sensibility in the retina appears to be extinguished, without any defect in the texture of the eye, any varicose dilatation of its blood-vessels, or any particular determination of blood to it. Applications producing an evacuation of lymph, including both blisters and antimonial ointment, may be alternately employed upon the eyelids and temples, when there are grounds for believing that the functions of the skin have already been long suspended by porrigo, or the stoppage of perspiration on the forehead.—(*Beer, Lehre von den Augenkr. b.* 2, *p.* 474.)

As in the rational plan of treatment, the rubbing of fluid, pungent or irritating medicines upon the eyebrows, in certain kinds of amaurotic blindness, is often attended with considerable efficacy; so, in Beer's opinion, it should not be neglected in cases where the surgeon is compelled to have recourse to empirical methods of cure; for instance, where it is observable that generally in the evening, or the shade, the eyesight immediately grows weaker; that on the patient's first awaking in the morning, it is weaker than in the middle of the day; and, what particularly merits notice, while the case is unattended with any sensations of imaginary flashes of light; a very feeble or entirely abolished motion of the iris; not the least vestige of any defect in the structure of the eye; and no symptoms of determination of blood to the head and eyes, or of a general tendency to inflammation. Beer recommends pungent applications to be first tried, such as the spiritus aromaticus, or Cologne water. These may be followed by aqueous substances, naphtha, &c.; then by narcotics, like the tincture of opium; and lastly, by irritating remedies, like the tinctura lyttæ. The tincture of iodine I should also consider an application well deserving of trial. Fluid applications which are applied in the form of vapour to the eye demand greater circumspection, like naphtha, the liquor ammoniæ, &c. These may be best applied by putting a small quantity of them into the hand, over which the eye must be held in such a manner that none of the fluid will come into contact with it. But as soon as the eye begins to be irritated by the vapour, the tears to run, or actual pain is felt, the hand is to be removed, lest too much irritation be produced.—(*Beer, vol. cit. p.* 475.)

Not only in the empirical, but also in every scientific mode of treating amaurosis, says this author, such remedies as are intended to produce a shock upon the nerves and vessels require the utmost caution, because, of all the various classes of remedies, they are the most powerful; and consequently, if misapplied, are likely to convert an amaurotic weakness of sight into complete blindness. This mournful event is most rapidly produced when applications of this description are employed in plethoric subjects affected with partial determinations of blood and local inflammations, a varicose state of the blood-vessels of the eye, defects in the transparent media of that organ, or frequent headache. To this class of remedies belong especially the

shower bath, electricity, galvanism, &c. On the empirical plan, they can only be used with safety or advantage when decided marks of paralysis, either in the amaurotic eye or its appendages, are present.—(*Lehre von den Augenkr. b.* 2, *p.* 477.)

Mr. Ware has observed that the pupil has been generally dilated in the cases benefited by electricity. He notices, however, that there are many instances in which a contraction of the pupil is the only change which takes place in the appearance of the eye. In this sort of case, the impairment of sight is usually preceded by severe pain, and the original cause may be an internal ophthalmy of long continuance. The crystalline is sometimes visibly opaque. Here electricity has been found useful; but Mr. Ware states, that in these instances the sublimate has proved superiorly and more certainly efficacious, and consequently he prefers it to all external applications whatever. He recommends one-fourth of a grain as a quantity proper for a common dose, and says that it agrees best with the stomach when first dissolved, as Van Swieten directs, in half an ounce of brandy, and taken in a basin of sago or gruel. For young patients the dose must be diminished in proportion to their youth. The medicine is to be continued as uninterruptedly as the constitution will allow, for a month, six weeks, or even longer.

Electricity is said to have proved more strikingly useful in cases of amaurosis originating from lightning, than when the disease has arisen from any other cause. Mr. Ware relates a most interesting instance of the success of electricity in a case which came on very suddenly after great pain in the teeth and a swelling of the face had gone off. The disorder came on more suddenly, the temporary blindness was more entire, the eyelids were more affected, and the cure more speedy, than in the instances related by Mr. Hey, in the 5th vol. of the *Med. Obs. and Inq.*—(*Chir. Observ. relative to the Eye, by J. Ware, vol.* 1.) However, the amaurosis produced by lightning may also be sometimes cured in other ways. Mr. Wardrop mentions that he has only seen one case of this kind, and the sight was restored by the repeated application of small blisters over the frontal nerve.—(*Essays on the Morbid Anatomy of the Human Eye, vol.* 2, *p.* 173.)

With the exception of one case related by Valsalva, Scarpa was unacquainted with any instance of amaurosis, arising from a wound of the eyebrow, that was relieved, and he has, therefore, set down this species as incurable. The opinion, however, is not perhaps correct; for the first case related by Mr. Hey arose from this cause, and was cured by giving every night the following dose: ℞. *Calomel. camphor.* à à gr. iij. *Conserv. cynosb.* q. s. *probe misceant et f. bolus*, in conjunction with electricity. The lady, however, had been previously bled twice, had taken some nervous medicines, and had had a blister between the shoulders. The patient was first set upon a stool with glass feet, and had sparks drawn from the eyes and parts surrounding the orbits, especially where the superciliary and infra-orbitary branches of the fifth pair of nerves spread themselves. After this operation had been continued half an hour, she was made to receive, for an equal time, slight shocks through the affected parts. In a few days, sight began to return, and in less than three months it was quite restored. In another case, one grain of calomel and two of camphor given every night, and the employment of electricity, effected a cure. The disease had come on gradually, without any previous accident or pains in the head. The patient was a boy nine years old.

There are several other very interesting cases of amaurosis related by Mr. Hey, all of which make electricity appear an efficacious remedy, though it is true, as Scarpa observes, that in most of these instances internal medicines were also given, and bleeding occasionally practised. Mr. Hey attributes the benefit chiefly to the electricity, because, in two of his cases, no medicines were used, yet the progress of the amendment seemed to be as speedy in them as in the rest; and in two instances a degree of sight was obtained by the first application of electricity. At present, I think electricity and galvanism, as means of benefiting amaurosis, are less valued in England than on the continent. Mr. Travers states, that he has had recourse to them in many cases, some of which were of a very favourable description, but he never saw any good produced by them.—(*Synopsis of the Diseases of the Eye, p.* 303.)

How far, however, the statements of Beer, Ware &c., about the efficacy of local applications, can be trusted, is yet a question; for they disagree with reports made by other writers. Thus, with the exception of cupping, issues, setons, and particularly blisters, Mr. Travers declares, that his experience leads him to attach no value to the various forms of external remedies.—(*Synopsis, &c. p.* 30, 8*vo. Lond.* 1820.)

H

HÆMATOCELE. (From αἷμα, blood, and κήλη, a tumour.) A swelling of the scrotum, or spermatic cord, proceeding from, or caused by, blood.

According to Mr. Pott, when the tunica vaginalis has been long or much distended, "it becomes thick and tough; and the vessels (especially those of its inner surface) are sometimes so large as to be very visible, and even varicose. If one of these lies in the way of the instrument wherewith the palliative cure is performed, it is sometimes wounded; in which case the first part of the serum which is discharged is pretty deeply tinged with blood.

Upon the collapsion of the membranes, and of the empty bag, this kind of hemorrhage generally ceases, and nothing more comes of it. But it sometimes happens, either from the toughness of the tunic, or from the varicose state of the vessel, that the wound (especially if made by a lancet) does not immediately unite; but continues to discharge blood into the cavity of the said tunic, thereby producing a new tumour, and a fresh necessity of operation."

This is what Mr. Pott calls the first species of hæmatocele, which evidently proceeds from a wound of a vessel of the vaginal tunic.

"Upon the sudden discharge of the fluid from the bag of an over-stretched hydrocele, and thereby removing all counter-pressure against the sides of the vessels, some of which are become varicose, one of them will sometimes, without having been wounded, burst; hence the last running of water from a hydrocele is often bloody. If the quantity of blood shed from the vessel so burst be small, it is soon absorbed again; and creating no trouble, the thing is not known. But if the quantity be considerable, it, like the preceding, occasions a new tumour, and calls for a repetition of the operation." This Mr. Pott calls the second species, "which, like the first, belongs entirely to the vaginal coat, and has no concern either with the testicle or with the spermatic vessels. In both, the bag, which was full of water, becomes in a short space of time distended with blood; which blood, if not carried off by absorption, must be discharged by opening the containing cyst; but in neither of these can castration (though said to be the only remedy) be ever necessary; the mere division of the sacculus, and the application of dry lint to its inside, will in general, if not always, restrain the hemorrhage, and answer every purpose for which so severe a remedy has been prescribed." With respect to filling the cavity of the tunica vaginalis with lint, I believe few good surgeons of the present day would consider the measure at all necessary or proper. I have seen three or four cases of hæmatocele of the above kind laid open, but never knew the surgeon compelled by the bleeding to cram the tunica vaginalis with lint, to the great irritation and injury of the testicle itself. On the contrary, after taking out the blood, letting the parts collapse, and applying the cold lotio plumbi acetatis for a few hours to the scrotum, by means of linen wet with the application, the surgeon substituted for the lotion an emollient poultice, and had recourse to fomentations, saline purgatives, leeches and even venesection, according to circumstances.

The next example regarded by Pott and Richter as a form of hæmatocele, is not admitted by Richerand, Jourdan (see *Dict. des Sciences Méd. t.* 20, *p* 126), and other modern surgeons.

"If," says Mr. Pott, "blood be extravasated within the tunica albuginea, or proper coat of the testicle, in consequence of a great relaxation and (as it were) dissolution of part of the vascular compages of that gland, and the quantity be considerable, it will afford or produce a fluctuation to the hand of an examiner very like to that of a hydrocele of the tunica vaginalis; allowing something for the different density of the different fluids, and the greater depth of the former from the surface.

If this be mistaken for a simple hydrocele, and an opening be made, the discharge will be blood; not fluid or very thin; not like to blood circulating through its proper vessels; but dark and dusky in colour, and nearly of the consistence of thin chocolate (like to what is most frequently found in the imperforate vagina). The quantity discharged will be much smaller than was expected from the size of the tumour; which size will not be considerably diminished. When this small quantity of blood has been so drawn off, the testicle will, upon examination, be found to be much larger than it ought to be, as well as much more loose and flabby: instead of that roundness and resistance arising from a healthy state of the gland, within its firm strong coat, it is soft, and capable of being compressed almost flat, and that generally without any of that pain and uneasiness which always attend the compression of a sound testicle. If the bleeding ceases upon the withdrawing the cannula (supposing a trocar to have been used), and the puncture closes, a fresh accumulation of the same kind of fluid is soon made, and the same degree of tumefaction is produced as before the operation; if the orifice does not close, the hemorrhage continues, and very soon becomes alarming."

In the first two species, "the blood comes from the tunica vaginalis, the testis itself being safe and unconcerned, and the remedy is found by opening the cavity of the said tunic; but in this the hemorrhage comes from the substance of the testicle; from the convolutions of the spermatic artery within the tunica albuginea: the division of the vaginal coat can here do no good; and an incision made into the albuginea can only increase the mischief; the testicle is spoiled, or rendered useless, by that kind of alteration made in it previous to the extravasation; and castration is the only cure which a patient in such circumstances can depend upon."

I confess that no good reason appears for arranging cases of the preceding kind with hæmatocele; for what are they but diseased testicles which have been punctured, either on account of their seeming to contain a fluid, or really having within them cysts filled with a chocolate-coloured or other fluid, as I have seen in hundreds of instances of sarcocele, and whatever blood is discharged is not extravasated in the substance of the testis previously to the puncture, but issues as a necessary consequence of that proceeding: however, of the propriety of the practice advised by Mr. Pott, no doubt can be entertained.

The last species of this disease noticed by Mr. Pott "arises from a bursting of a branch of the spermatic vein, between the groin and scrotum, in what is generally known by the name of the spermatic process. This, which is generally produced by great or sudden exertions of strength, feats of agility, &c., may happen to persons in the best health, whose blood and juices are in the best order, and whose genital parts are free from blemish or disease.

The effusion or extravasation is made into the cellular membrane, which invests and envelopes the spermatic vessels, and has something the appearance of a true hernia. When the case is clear, and the extravasated blood does not give way to discutient applications, the only remedy is to lay the tumour fairly open through its whole length. If the vessel or breach be small, the hemorrhage may be restrained by mere compression with dry lint, or by the use of styptics; but if it be large, and these means do not succeed, the ligature must be made use of."

I cannot conceive, that in any case of a mere rupture of one of the spermatic veins, it can ever be justifiable to tie the whole spermatic cord, and then perform castration; though Mr. Pott advises this plan, in case the bleeding branch cannot be tied singly. Discutient applications, and an occasional purge, will almost always disperse the swelling; and if not, opening it, taking out the blood, applying cold, or, if necessary, filling the cavity with lint, and using compression, would be, according to my humble judgment, the most judicious treatment.

A case precisely of the latter kind is not very common, yet Mr. Pott has not omitted it as one of the forms of hæmatocele: but why he has not taken notice of the most frequent of all the varieties of the disease, I am at a loss to conjecture; I mean the extravasation of blood in the loose cellular membrane of the scrotum from blows on the part, and sometimes from lithotomy, castration, &c., quite unconnected with any rupture of the spermatic veins. These are the cases which are mostly met with in practice. I have seen them followed by suppuration; but in general the effused blood is gradually absorbed, with the aid of discutient applications, leeches, fomentations, poultices, and saline purges. A surgeon should generally be reluctant to lay open the tumour, as, in many instances, sloughing and very severe symptoms have been the result.

Celsus and Paulus Ægineta are the best of the old writers on hæmatocele. For modern information, consult Pott's Chir. Works, vol. 2. *B. Bell, On Hydrocele. Flajani, Collezione d'Osservazioni, &c., t.* 2. *Richter, Anfangsgr. der Wundarzn. b.* 6. *Richerand, Nosographie Chir. t.* 4. *Ossiander, in Arnemann's Magazin für die Wundarzn. b.* 1, *p.* 355; *the patient died after an opening had been made in the swelling. HARE-LIP. (*Labia Leporina.*) A fissure or perpendicular division of one or both lips. The term has arisen from the fancied resemblance of the part to the upper lip of a hare. Occasionally the fissure is more or less oblique. In general, it is directly below the septum of the nose; but sometimes it corresponds to one of the nostrils. The two portions of the lip are generally moveable, and not adherent to the alveolary process; in less common cases they are closely attached to the fore part of the jaw.

Children are frequently born with this kind of malformation, which is called a *natural* hare-lip, while that which is produced by a wound is named *accidental.* Sometimes the portions of the lip, which ought to be united, have a considerable interspace between them; while in other instances they are not much apart. The cleft is occasionally double, a little lobe or small portion of the lip being situated between the two fissures.

The fissure commonly affects only the lip itself, and usually the upper one. In many cases, however, it extends along the bones and soft parts forming the palate, even as far as the uvula; and sometimes those bones are entirely wanting. In a few instances, the jaw not only is imperfectly ossified in front, so that a cleft presents itself there, but one side of it projects forwards, and is at the same time inclined too much outwards, drawing with it the corresponding part of the palate, and the septum nasi, so that a very unsightly distortion of the nostril and nose is produced. The case, I believe, has not been described in surgical books.

A hare-lip, in its least degree, occasions considerable deformity; and when more marked, it frequently hinders infants from sucking, and makes it indispensable to nourish them by other means. When the lower lip alone is affected, which is rare as a malformation, the child can neither retain its saliva, nor learn to speak, except with the greatest impediment. The constant escape of the saliva, besides being an annoyance, is found to be detrimental to the health; for its loss impairs the digestive functions, the patient becomes emaciated, and even death would sometimes ensue, if the incessant discharge of so necessary a fluid in the animal economy were not prevented. Thus, a lady, who was in this state, consulted Trouchin, who immediately saw the cause of her indisposition, and recommended the fissure in the lip to be united; the operation was done, and the dyspeptic symptoms then ceased. And when the fissure pervades the palate, the patient not only articulates very imperfectly, but cannot masticate nor swallow, except with great difficulty, on account of the food readily getting up into the nose.

An early removal of the deformity must obviously be

very desirable, but, as it cannot be accomplished without an operation attended with some degree of pain, Dionis, Garengeot, and others advise waiting till the child is four or five years old, on the supposition that, at an earlier age, the child's agitations and cries would render the operation impracticable, or derange all the proceedings taken to ensure its success. It is plain, however, that such reasons are not of great weight. A child, four or five years old, and very often even one eight or ten years of age, is more difficult to manage than an infant only a few months old. Every child of the above age has a thousand times more dread of the pain, than of the deformity or of the inconveniences of the complaint, to which he is habituated; while an infant of tender years fears nothing, and only feels the pain of the moment.

A more rational objection is the liability of infants to convulsions after operations, and this has induced many excellent surgeons to postpone the cure of the hare-lip till the child is about two years old. This custom is also sanctioned by Sir Astley Cooper, who mentions in his lectures several instances, which have either been communicated to him by others, or have occurred in his own practice, where operations for the cure of hare-lips in very young infants have had a fatal termination, in consequence of an attack of convulsions or diarrhœa. The period when dentition is completed, or the age of two years, he therefore sets down as the most advantageous for the operation, and if parents urge its being done earlier, he very properly advises the surgeon to let them be duly apprized of the risk, so that in the event of the child being cut off, he may not incur blame for having operated at a disadvantageous period of life.—(See *Lancet*, *vol.* 3, *p.* 108.) The latter end of 1823, I met Sir Astley Cooper in consultation in a case where this very question occurred. The deformity was particularly unsightly, in consequence of the upper jaw-bone being imperfectly ossified in front, and one side of it forming a considerable projection forwards through the fissure which extended into the nostril, at the same time that the nose was seriously distorted to one side of the face. The parents, persons of the first respectability, were therefore uncommonly solicitous for an early operation, some instances of the success of which in very young infants had already been communicated to them by their friends. The projection of bone, they had also learned, might be cut away, so as to permit the soft parts to meet, which they now would not do. The risk of an operation on the infant in question, then scarcely two months old, was fairly explained to the parents; but I doubt whether they could have been prevailed upon to wait three months longer, had not Sir Astley Cooper represented to them the disadvantages of cutting away the bony projection, and urged the allowance of a little time to reduce the protuberance by means of pressure. As I had not had any previous conference with Sir Astley on the subject, I was particularly gratified in finding his advice agree precisely with what I had already given, when the case was first shown to me. Exactly when the infant was five months old, a period selected on account of its being the latest previously to the usual time of the commencement of the ailments of dentition, I performed the operation in the presence of Messrs. Ives, of Chertsey, and Mr. Ives, jun., of Chobham. By this time the bone had been so effectually depressed, by means of a kind of spring-truss, constructed by Messrs. Salmon and Ody for the purpose, and worn several hours daily, that the soft parts admitted of being brought over it with tolerable facility. Union followed very well, and, though it was one of the worst hare-lips ever seen by Mr. Ives, senior, or myself, without an extensive division of the palate, the disfigurement is now very trivial, and the wrong direction of the nose constantly undergoing farther diminution, in proportion as the jaw recedes under the pressure of the apparatus, which is still employed.

This is the youngest infant on which I have operated; but, in October, 1824, I performed the operation on an infant twelve months old, at Walton on Thames, where I was kindly assisted by Mr. Stillwell, surgeon in that town. Union took place very favourably, without any indisposition whatever. Only one pin was used at the lower part of the lip, as I found that the upper part of the division could be perfectly and readily closed with a strip of adhesive plaster.

Mr. Sharp observes, "there are many lips where the loss of substance is so great, that the edges of the fissure cannot be brought together, or at best where they can but just touch; in which case it need not be advised to forbear the attempt: it is likewise forbid in young children, and with reason, if they suck; but otherwise it may be undertaken with great safety, and even with more probability of success than in others that are older."—(*Operations in Surgery*, *chap.* 34.)

Le Dran performed the operation on children of all ages, even on those at the breast. B. Bell did it with success on an infant only three months old. Muys advises it to be undertaken as soon as the child is six months old. Roonhuysen operated on children ten weeks after their birth, and all his contemporaries have praised his singular dexterity and success. As an essential step to the success of the operation, he recommended hindering the children from sleeping a certain length of time before it was undertaken, in order that they might fall asleep immediately afterward; and with the same view opiates have been prescribed.

Putting out of consideration the partial success which has attended the use of blistering plaster for making the edges of the fissure raw and capable of union, all practitioners entertain the same sentiment with regard to the object of this operation, which consists in reducing the preternatural solution of continuity to the state of a simple wound, by cutting off the edges of the separated parts throughout their length, and then keeping these parts in contact until they have completely grown together. But although such principles have been generally admitted, there was formerly some difference of opinion with respect to the best method to be followed in practice; some operators having preferred sutures for keeping the edges of the wound in contact; while others disapproved of them, believing that a perfect cure might always be accomplished by means of adhesive plaster and a uniting bandage, so as to save the patient from all the pain and annoyance of sutures.

M. Louis thought that the use of sutures in the operation for the hare-lip proceeded from a false idea respecting the nature of the disease; for, the fissure in the lip being wrongly imputed to loss of substance, it was deemed impossible to keep the parts in contact, except by a suture.

"The separation of the edges of the fissure in the lip," says M. Louis, "is only the effect of the retraction of the muscles, and is always proportioned to the extent of the cleft. Persons with hare-lips are capable of bringing the edges of the fissure together by muscular action, by puckering up their mouths. On the other hand, the separation is considerably increased when they laugh, and the breach appears excessively large after superficially paring off its edges on both sides. The interspace in the hare-lip must not, therefore, be mistaken for a loss of substance. This truth is confirmed by the effects of sticking-plaster, which has sometimes been applied to the hare-lip, as a preparatory measure before the operation, and which materially lessens the separation of the parts.

According to the confession of all who have written in favour of the twisted suture, it seems advisable only on the false idea, that the hare-lip is the effect of a greater or less loss of substance: and they say, positively, that we must not have recourse to it when there is only a simple division to be united. The twisted suture must then be proscribed from the operation for the natural hare-lip, since it is proved that this malformation is unattended with loss of substance. At the same time, a loss of substance is but too real, after the extirpation of scirrhous and cancerous tumours, to which the lips are very subject. Yet, even in these cases, the extensibility of the lips allows an attempt to be made to reunite the double incision, by which the tumour has been removed, and it succeeds without the smallest deformity, when care is taken to direct each incision obliquely, so that both of them form, where they meet, an acute angle, in the base of which the tumour is comprised. Here the means of union ought to be the more efficacious, because the difficulty of keeping the edges of the wound approximated is greater. M. Pibrac, in his memoir on the abuse of sutures, when speaking of the hare-lip, has already explained, that they are badly-conceived means, and more hurtful in proportion as there is a greater loss of substance, because the greater the interspace is between the two parts, the more fear is there of their efforts on the

needles or pins left in the wound. Hence, care has always been taken to make the dressings aid the operation of the suture. After this consideration, judiciously made by the partisans of this plan, there was only one more step to be taken, according to M. Pibrac, in order to evince the necessity of proscribing it. The cap or copper headpiece described by Verduc and Nuck, for compressing the cheeks; the clasps of Heister; and strips of adhesive plaster; are all only inventions for the support of the parts, and keeping them from being disunited. When the suture failed, it was by these means that the original deformity was corrected, together with that produced by the laceration, which would not have occurred without the suture. As then, the dressings, when methodically applied, are capable of effectually rectifying the mischief of the suture, M. Louis inquires, why should they be considered only as a resource in a mere accidental case? Why should they not be made the chief and primary means of reuniting the lip, even when there is a loss of substance?

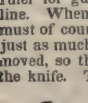
Nothing can be opposed to the proofs adduced upon this point. They are even drawn from the practice of those who have employed sutures without success. Such persons have themselves furnished the proofs of the bandage being capable of repairing the mischief resulting from the twisted suture."

M. Louis, with a view of perfecting our notions on this matter, lays it down as a fact, that the retraction of the muscles being the cause of the separation of the edges of the fissure, it is not to these edges we are to apply the force which is to unite them; but that it should be applied farther to the very parts, whose action (the cause of the separation) is to be impeded, and whose contraction is thus to be prevented. A great many means for supporting the wound, only irritate the muscles and excite them to action, and it is this action which we should endeavour to overcome. The means for promoting union can only be methodical, when directly employed to prevent such action, by an immediate application on the point where it is to be resisted. The facility with which the parts may be brought forwards, so as to bring the two commissures of the lips into contact by the mere pressure of the hands, shows what may be expected from a very simple apparatus, which will execute the same office without any effort, in a firm and permanent manner, and which will render sutures unnecessary, the inconveniences of which are too well known.

M. Louis, after having explained the reasons of the theory on which he founded his method, relates several cases, taken either from his own practice or that of others, to illustrate its advantages. He details the history of twenty cases in which his plan perfectly succeeded, both in accidental hare-lips, with considerable loss of substance, and in natural ones. In most of these instances, however, it was thought proper to assist the bandage with one stitch at the extremity of the fissure, close to the vermilion border of the lip, for the purpose of keeping the parts securely on a level.

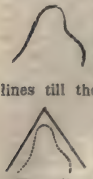
Notwithstanding the operation as performed with the twisted suture is opposed by an authority of such weight as that of M. Louis, still it is the method most commonly practised. No modern surgeons doubt that a hare-lip may be cured by means of adhesive plaster and uniting bandages, quite as perfectly as with a suture; and all readily allow, that the first of these methods, as being more simple and less painful, would be preferable to the latter one, if it were equally sure of succeeding. But it is considered far more uncertain in its effect. To accomplish a complete cure, the parts to be united must be maintained in perfect contact, until they have contracted the necessary adhesion; and how can we always depend upon a bandage for keeping them from being displaced? What other means, besides a suture, affords in this respect perfect security?

I shall first describe the operation as usually done by surgeons of the present day with the twisted suture. The first thing is to examine whether there is any adhesion of the lip to the gum; and if there be, to divide it with a knife. Some authors (*Sharp*) recommend the frænulum, which attaches the lip to the gum, always to be divided: but when the hare-lip is at some distance from this part, it will not be in the way of the operation, and need not be cut. On the other hand, when the frænulum is situated in the centre of the division, it is clear that in operating, we must necessarily include it in the incision, and it should therefore be divided beforehand, taking care not to encroach too much upon the gum, lest the alveolary process be laid bare; nor too much upon the lip, because making it thinner would be unfavourable to its union.



When one of the incisor teeth opposite the fissure projects forwards, it must be drawn, lest it distend and irritate the parts after they have been brought into contact.

Sometimes, but particularly in cases in which there is a cleft in the bony part of the palate, a portion of the os maxillare superius forms such a projection just in the situation of the fissure in the lip, that it would render the union very difficult, if not impracticable. In this circumstance, the common plan has been to cut off the projecting angles of bone with a strong pair of bone-nippers. The part was then healed, and the operation for the hare-lip performed. Instead of cutting off the projection of bone, which is always a painful measure, Desault used to employ simple compression, by which means the prominence was usually reduced in a few weeks, and the opportunity afforded of operating for the cure of the hare-lip.—(*Œuvres Chir. par Bichat, t. 2, p.* 207.) Of course, the actual necessity of using bone-nippers, or even of having recourse to compression of the bony projection, will depend upon circumstances; for if the prominence of bone be sharp and irregular, no surgeon, I conceive, would hesitate about the removal of such inequalities in preference to the trial of pressure. Mr. Dunn, of Scarborough, has expressed to me his doubts whether cutting off the projections of the alveolary process be ever necessary, as the pressure of the entire lip gradually diminishes the deformity. "I had (says he) two very unseemly cases, with an immense division of the palate, together with a projection of the alveolary process, which, with the incisor teeth, resembled the talons of a bird. A tubercular appendage of skin hung upon the base of the nose. By drawing the teeth in the first case very delicately, I avoided fracturing the bony projection. I then cut off one edge of the nasal appendage, and of the lip on the same side, and attached them together with two needles. The wound was sufficiently united in a week or ten days to allow the same operation on the other side. In less than three weeks the boy was sent home quite well, to the astonishment of the neighbourhood, where his frightful appearance had made him an object of disgust and ridicule. I succeeded in the other case even without the extraction of the teeth. Both the patients can now articulate labial sounds, retain their saliva, and are gradually losing the inconvenience of the passage of the mucus from the nose into the mouth, as the fissure is more contracted, and the projection by no means so disagreeable." These facts should lessen the haste with which certain operators proceed to cut off every projection of the alveolary process; for a moderate prominence of bone without any sharp, irritating edges or angles, will not hinder the success of the operation; and even the propriety of removing teeth must entirely depend upon their being likely, by their direction, to irritate the lip, and disturb the union of the fissure.



One serious objection to cutting away the projection of the jaw is the deformity afterward likely to continue during life from the deficiency of the incisores teeth; and another is, the subsequent overlapping of the lower jaw, and its projection beyond the upper one; communicating to the mouth an appearance seen in very old subjects. These were the considerations which induced me, in the case above mentioned, to employ pressure, which is much more conveniently applied by means of a kind of spring-truss, adapted to the child's head, than with bandages, which would be seriously annoying, and the right action of which could not be regulated without the utmost difficulty. When also some of the bone must be cut away on account of its roughness and angular prominences, I advise the practitioner to remove only the irritating points, and afterward have recourse to pressure.

In the operation, the grand object is to make as smooth and even a cut as possible, in order that it may more certainly unite by the first intention, and of such a shape that the cicatrix may form only one narrow line. The edges of the fissure should, therefore, never be cut off with scissors, which constantly bruise the fibres which they divide, and a sharp knife is always to be preferred. The best plan is, either to place any flat instrument, such as a piece of horn wood, or

pasteboard, underneath one portion of the lip, and then holding the part stretched and supported on it, to cut away the whole of the callous edge; or else to hold the part with a pair of forceps, the under blade of which is much broader than the upper one: the first serves to support the lip, the other contributes also to this effect, and, at the same time, serves as a sort of ruler for guiding the knife in an accurately straight line. When the forceps are preferred, the surgeon must of course leave on the side of the upper blade just as much of the edge of the fissure as is to be removed, so that it can be cut off with one sweep of the knife. This is to be done on each side of the cleft, observing the rule, to make the new wound in straight lines, because the sides of it can never be made to correspond without this caution. For instance, if the hare-lip had this shape, the incision of the edges must be continued in straight lines till they meet in the manner here represented.

In short, the two incisions are to be perfectly straight, and are to meet at an angle above, in order that the whole track of the wound may be brought together, and united by the first intention.

Two silver pins, made with steel points, are next to be introduced through the edges of the wound, so as to keep them accurately in contact; the lowest pin being introduced first, near the inferior termination of the wound, and the upper pin afterward, about a quarter of an inch higher up. A piece of thread is then to be repeatedly wound round the ends of the pins, from one side of the division to the other, first transversely, then obliquely, from the right or left end of one pin above, to the opposite end of the lower one, &c. Thus the thread is made to cross as many points of the wound as possible, which greatly contributes to maintaining its edges in even apposition. Any portion of the wound above the pins not closed by the preceding means may now have its edges brought together with a strip of adhesive plaster. Lastly, the ends of the pins are to be supported by small dossils of lint, placed between them and the flesh; a minute but essential circumstance, which, as my friend Mr. Dunn, of Scarborough, reminds me, I forgot to mention in a former edition of this work. It is obvious that a great deal of exactness is requisite in introducing the pins, in order that the edges of the incision may afterward be precisely applied to each other. For this purpose, some surgeons previously place the sides of the wound in the best position, and mark with a pen the points at which the pins should enter and come out again; a method which, as far as my observations extend, merits imitation. The pins ought never to extend more deeply than about two-thirds through the substance of the lip, and it would be a great improvement always to have them of a flat, instead of a round shape, and a little curved, as this is the course which they naturally ought to take when introduced. The steel points should also admit of being easily taken off, whenthe pins have been applied; and, perhaps, having them to screw off and on is the best mode, as removing them in this way is not so likely to be attended with any sudden jerk which might be injurious to the wound, as if they were made to pull off. In general, the pins may be safely removed in about four days, when the support of sticking plaster will be quite sufficient.

After the operation, the surgeon should never omit the use of compresses and a bandage for keeping forward the cheeks, so that the risk of the pins making their way out by ulceration, arising from the dragging of the soft parts on them, may be prevented. With this view, a close, strong nightcap, with a piece of broad tape attached to the back part of it, and with two ends of sufficient and equal length, is to be put on; a compress is then to be laid over one cheek, and fixed by bringing one portion of the tape forwards over it, which is to be fastened to the cap on the opposite side of the head. The other compress is then to be applied, and fixed in a similar manner. Lastly, a bandage is to be put under the chin, and brought over each compress up to the top of the head, where the ends of it are to be fastened to the cap. During all these proceedings, until the compresses are well secured, the assistant must support them steadily with his hands. Lastly, the bandage, compresses, and cap should all be securely stitched together.

The process just described is what is well known by the name of the *twisted suture*, which is applicable to other surgical cases, in which the grand object is to heal some fistula or opening by the first intention. Mr. Sharp says, it is of great service in fistulæ of the urethra, remaining after the operation for the stone, in which case the callous edges may be cut off, and the lips of the wound held together by the above method.

Although the generality of surgeons used the twisted suture, I ought to notice that Sir A. Cooper gives the preference to the common interrupted suture, on account of the difficulty sometimes experienced in withdrawing the pins, and the liability of the new adhesions to be broken on the occasion; whereas the threads of a common suture may be cut and taken out with the greatest facility.—(See *Lancet, vol.* 3, *p.* 107.) However, as most children cry on the removal of the suture, whether one kind or the other be employed, the only safe plan is not to withdraw the pins or ligatures till four complete days have elapsed from the time of the operation, when the adhesions will be tolerably strong; and the cheeks should always be held forwards by a skilful assistant during the period of changing the dressings, and until the compresses on the cheeks have been again duly secured with a bandage.

[When pins are used in this operation, they ought to be made of gold, which is not liable to become oxidized. Instead, however, of these pins, which are ordinarily made with steel points, Dr. Barton, of Philadelphia, prefers to use a piece of iron wire, with a point made by simply cutting it with a pair of scissors; thus avoiding the risk of the steel point slipping off the pin, an accident which has often happened, and left the point within the lip.

So many failures have occurred from the pins being torn out by the child, or catching in the nurse's clothes, that if there were no other objection to the use of pins, they ought to be abandoned. Many surgeons in this country (and among these Dr. Mott) have adopted the interrupted suture in cases of hare-lip, and with the most satisfactory results; and it is confidently believed that the twisted suture ought to be abandoned, on account of the obvious objections which attach to every modification of the shape, configuration, and materials of the pins. It will be seen that Sir A. Cooper has laid it aside altogether.—*Reese.*]

What has hitherto been stated refers to the most simple form of the hare-lip, viz. to that which presents only one fissure. When there are two clefts, the cure is accomplished on the same principle, but it is rather more difficult of execution; so that the old surgeons, until the time of Heister, almost all regarded the operation for the double hare-lip as impracticable. Only a few described it, with the direction to operate on each fissure, just as if it were single. M. de la Faye even operated in this way with success.—(*Mém. de l'Acad. de Chir. t.* 4, 4*to.*) M. Louis was of opinion, that all difficulties would be obviated by doing the operation at two different times, and awaiting the perfect cure of one of the fissures before that of the other was undertaken. Heitster had similar ideas, but he never put the scheme in practice, nor did he even positively advise it.

After all, however, experience proves that it is not essential to perform two operations for the cure of the double hare-lip. Desault found that when the edges of the two fissures were pared off, and care taken to let one of the pins pass across the central piece of the lip, the practice answered extremely well.—(See *Œuvres Chir. t.* 2, *p.* 201.)

In cutting off the edges of the fissure, the incision must be carried to the upper part of the lip; and even when the fissure does not reach wholly up the lip, the same thing should be done; for in this manner the sides of the wound will admit of being applied together more uniformly, and the cicatrix will have a better appearance. We should also not be too sparing of the edges, which are to be cut off. Practitioners, says M. Louis, persuaded that the hare-lip was a division with loss of substance, have invariably advised the removal of the *callous* edges. But in the natural hare-lip, there is no callosity; the margins of the fissure are composed, like those of the lip itself, of a pulpy, fresh coloured, vermilion flesh, covered with an exceedingly delicate cuticle. The whole of the part having this appearance must be taken away, together with a little of the true skin. At the lower part of the fissure, towards the

nearest commissure, a rounded red substance is commonly situated, which it is absolutely necessary to include in the incision. Were this neglected, the union below would be unequal, and, through an injudicious economy, a degree of deformity would remain. The grand object, however, is to make the two incisions diverge at an acute angle, so that the edges may be put into reciprocal contact their whole length, without the least inequality.

M. Louis used to operate as follows: the patient being seated in a good light, his head is to be supported on an assistant's breast, who with the fingers of both hands pushes the cheeks forwards, in order to bring the edges of the fissure near to each other. These are to be laid on a piece of pasteboard, which is to be put between the jaw and lip, and be an inch and a half long, from twelve to fifteen lines broad, and at most one line thick. The upper end should be rounded by flattening the corners. In order to facilitate the incision, the lip is to be stretched over the pasteboard, the operator holding one portion over the right with the thumb and index finger of the left hand, while the assistant does the same thing on the left side. Things being thus disposed, the edges of the hare-lip are to be cut off with two sweeps of the bistoury, in two oblique lines, forming an acute angle above the fissure.

For the removal of the edges of the hare-lip, scissors have sometimes been preferred to a knife; but notwithstanding Desault's partiality to them, as most convenient (see *Œuvres Chir. t.* 2, *p.* 179), they are now very generally disused. The pinching and bruising which result from the action of the two blades are circumstances which cannot be favourable to the union of the wound; and though they may not commonly be serious enough to prevent union by the first intention, they might occasionally tend, with any other untoward occurrence, to hinder this desirable event. Let not practitioners here be led by Mr. B. Bell's statement, that in one instance he cut off one side of the fissure with a knife, and the other with scissors; that the latter cut produced least pain, and that on this side there was no more swelling nor inflammation than on the opposite one.

The pins should be introduced at least two-thirds of the way through the substance of the lip, lest a furrow should remain on the inside of the part, which might prove troublesome by allowing pieces of food to lodge in it. There is, however, a stronger reason for attending to this circumstance, viz. the hemorrhage which may take place when it is neglected. As soon as the edges of the wound have been brought together by means of the suture, and the pins are properly placed, the bleeding almost always ceases; but when the pins have not been introduced deeply enough, and the posterior surfaces of the incisions are not applied to each other, the blood may continue to run into the mouth, and give the surgeon an immense deal of trouble. In the memoir written by Louis, there is a case in which the patient died in consequence of such an accident. Persons who had undergone the operation were always advised to swallow their spittle, even though mixed with blood, in order to avoid disturbing the wound by getting rid of it otherwise. In the case alluded to, the patient, who had been operated upon for a cancerous affection of the lip, swallowed the blood as he had been directed to do, and he bled so profusely that he died. On the examination of the body, the stomach and small intestines were found full of blood. "This deplorable case," says the illustrious author who relates it, "deserves to be recorded for public instruction, for the purpose of keeping alive the attention of surgeons on all occasions, where, in consequence of any operation whatsoever, there is reason to apprehend bleeding in the cavity of the mouth. Platner is the only writer who, as far as I know, foresaw this kind of danger. The bleeding from the edges of the wound stops of itself (says he) as soon as they have been brought into contact and stitched together; but care must be taken that the patient does not swallow the blood, which might make him vomit, or else suffocate him. Hence, his head should be elevated that the blood may escape externally, a precaution more particularly necessary in young children."

Having described the mode of operating for the hare-lip as approved of by the generality of practitioners, and detailed every thing which seemed material, I have now only to explain the method adopted by M. Louis. His sentiments respecting several particular points of the operation have been already stated; and an account of the means which he employed in lieu of the twisted suture, for uniting the edges of the wound, is all that remains to be noticed.

Several bandages for supporting the two portions of the divided lip, and lessening the pressure which they make against the pins, have been mentioned by authors. Franco and Quesnay, in particular, describe two kinds. These means were not only employed as auxiliary, but even sometimes as curative ones, when it was impossible to use needles. To such bandages, too complicated and too uncertain in their effect, M. Louis prefers a simple linen roller, one inch wide, three ells long, and rolled up into two unequal heads. He begins with applying the body of this bandage to the middle of the forehead; he unrolls the two heads from before backwards, above the ears, between the upper part of the cartilage and the cranium, in order to let them cross on the nape of the neck, and then pass forwards again. The assistant who supports the head, and pushes forwards the cheeks, must lift up the ends of his fingers, in the place of which, on each side, a thick compress is to be put. This being covered, and pushed from behind forwards by the roller, will constantly perform the office of the assistant's fingers, who is to continue to support the apparatus, until it is all completely applied. The longest of the two heads of the roller being slit in two places near the lip, presents two parallel openings; the remnant of the shortest one is divided into two parts, as far as its end. The two little narrow bands in which it terminates must then pass through the openings of the former, and cross upon the middle of the lip. The ends of the roller being carried from before backwards, are then to be made to cross again on the nape of the neck, where the shortest is to end. The remainder of the long one is to be employed in making turns round the head. This bandage may be still more securely fixed by means of a piece of tape, which is to pass the forehead over the sagittal suture, and be pinned at each end to the circumvolutions of the roller; while a second piece of tape is to cross the first one at the top of the head, and also to be attached at its extremities to the uniting bandage, and the compresses placed under the zygomatic arches, for the purpose of pushing forwards the cheeks.

This bandage is extremely simple, and would answer well as an auxiliary to the twisted suture. I think this last means will always be the favourite of the practical surgeon, because the desired effect can be produced by it with much less trouble than must be taken with the bandage, in order to render the operation of the latter sufficiently certain. Besides, as I have noticed, M. Louis himself mostly made one stitch near the red part of the lip, so that he cannot be said to have trusted altogether to the bandage.

What has been said concerning the operation for the hare-lip, is equally applicable, not only to the treatment of cancer of the lip, but also to that of accidental cuts or lacerations of this part, from any cause whatsoever. We shall only remark, that in a recent wound, all the surgeon has to do, is to apply the twisted suture and adhesive plaster without delay.

When there is a fissure in the bones forming the roof of the mouth, it usually diminishes, and gradually closes, after the hare-lip is cured. But this does not always happen, and when the parts remain so considerably separated as to obstruct speech and deglutition, or cause any other inconvenience, a plate of gold or silver, exactly adapted to the arch of the palate, and steadied by means of a piece of sponge fixed to its convex side and introduced into the cleft, may sometimes be usefully employed. When the sponge is of suitable size and very dry before being used, the moisture of the adjacent parts will make it swell, and in many cases be sufficient to keep it in its situation, so as greatly to facilitate speaking and swallowing. Sometimes, however, the fissure is so shaped that the sponge cannot be fixed in it: this principally happens when the opening widens very much towards the front of the jaw. In such cases, it has been proposed to fix a plate of gold by means of springs covered with the same metal. Platina, which is cheaper, might be used for the same purpose. The subject, however, of artificial palates is one on which much mechanical ingenuity may yet be usefully exerted, and it can hardly be expected that I should here do more than give refer

ences to works in which the reader may find information upon it.—(See *Fauchard, Le Chirurgien-Dentiste, 2 tom. 12mo. [The operation of staphyloraphy, or palate suture was first performed in 1816, by Professor Graefe, of Berlin, and soon afterward repeated in Paris by M. Roux.

Professor Warren, of Harvard University, was the first to perform it in this country, and Professor Stevens, of New-York, has since repeated it on a young man, æt. 25, for a frightful congenital division of the palate, with very satisfactory success. This latter case is reported at length in the New-York Medical and Surgical Journal, for April, 1827.—*Reese.*]

HEAD, INJURIES OF THE. From the variety of parts of which the scalp is composed, from their structure, connexions, and uses, injuries done to it by external violence become of much more consequence than the same kind of ills can prove, when inflicted on the common integuments of the rest of the body. One principal reason of the danger in these cases depends upon the free communication between the vessels of the pericranium and those of the dura mater, through the diploe of the skull; for when inflammation is kindled in the former membrane, it may extend itself to the latter. According to Sir Astley Cooper, there are three modes in which wounds of the scalp may induce fatal consequences. 1st, by producing what is called an erysipelatous inflammation on the head; 2dly, by producing extensive suppuration under the tendon of the occipito-frontalis muscle; 3dly, by rendering a simple fracture compound, so as to cause more extensive inflammation of the dura mater.—(*Lectures, vol.* 1, *p.* 350.) The latter observation, as far as my information reaches, is new, and deserves the serious consideration of the practitioner; for in the great hospital where I was educated, and in all the practice which I have seen in the army and elsewhere, no analogy of this kind was ever suspected between ordinary compound fractures and those of the cranium. If the doctrine be correct, it forms another weighty argument against the method of cutting down to a fracture of the skull without urgent motives.

Incised wounds of the scalp are, indeed, less liable than contused or lacerated ones to produce bad consequences; but they are not entirely devoid of danger; in proof of which, Sir Astley Cooper mentions the case of a lady of rank in the country who died from the removal of an encysted tumour of the scalp.—(*Lectures, vol.* 1, *p.* 349.) Passing over these cases, however, which generally heal as well the generality of cuts in the skin of other parts of the body, and require no particularity of treatment, Mr. Pott proceeds immediately to lacerated and punctured wounds. "The former may be reduced to two kinds: viz. those in which the scalp, though torn or unequally divided, still keeps its natural situation, and is not stripped nor separated from the cranium to any considerable distance beyond the breadth of the wound; and those in which it is considerably detached from the parts it ought to cover. The first of these, if simple, and not combined with the symptoms or appearances of any other mischief, does not require any particular or different treatment from what the same kind of wounds require on all other parts;" but with respect to those in which the scalp is separated and detached from the parts it ought to cover, Mr. Pott makes no scruple of declaring it as his opinion, that its preservation ought always to be attempted, *unless it be so torn as to be absolutely spoiled, or there are manifest present symptoms of other mischief.* In former days, the excision of the lacerated and detached scalp was the general practice; but Mr. Pott had so often made the experiment of endeavouring to preserve the torn piece, and so often succeeded, that he recommended it as a thing always to be attempted, even though a part of the cranium were perfectly bare.

Here I may remark that all practitioners now invariably avoid cutting away the scalp, even in the circumstances in which such practice was allowed by Pott. By *spoiled*, this eminent writer must mean so injured as necessarily to slough afterward. However, as no harm results from taking the chance of its not sloughing, which never can be with certainty foretold; and as the excision of the part is painful and productive of no benefit, even if sloughing must follow; such operation is, in every point of view, hurtful and wrong. With respect to other mischief, as a reason, the examination of the cranium, and even the application of the trephine, never require any of the scalp to be cut away.—(See *Trephine.*)

Let the surgeon, therefore, free the torn piece from all dirt or foreign bodies, and restore it as quickly and as perfectly as he can to its natural situation.

Notwithstanding Mr. Pott assents to the employment of sutures for uniting certain lacerated wounds of the scalp, the best practitioners of the present day generally employ only sticking plaster. Sometimes the loosened scalp will unite with the parts from which it is torn and separated, and there will be no other sore than what arises from the impracticability of bringing the lips of the wound into smooth and immediate contact, the scar of which sore must be small in proportion. Sometimes such perfect reunion is not to be obtained; in which case, matter will be formed and collected in those places where the parts do not coalesce: but this does not necessarily make any difference either in the general intention or in the event; this matter may easily be discharged by one or two small openings made with a lancet; the head will still preserve its natural covering; and the cure will be very little retarded by a few small abscesses.

In some cases (as Pott proceeds to describe), the whole separated piece will unite perfectly, and give little or no trouble, especially in young and healthy persons. In some, the union will take place in certain parts and not in others (also Brodie, in *Med. Chir. Trans. vol.* 14, *p.* 408); and consequently matter will be formed, and require to be discharged, perhaps at several different points; and in some particular cases, circumstances, and habits, there will be no union at all, the torn cellular membrane or the naked aponeurosis will inflame and become sloughy, a considerable quantity of matter will be collected, and, perhaps, the cranium will be denuded. But even in this state of things, which does not very often happen, where care has been taken, and is almost the worst which can happen in the case of mere simple laceration and detachment,

f the surgeon will not be too soon or too much alarmed, nor in a hurry to cut, he will often find the cure much more feasible than he may at first imagine: let him take care to keep the inflammation under by proper means, let him have patience till the matter is fairly and fully formed, and the sloughs perfectly separated, and when this is accomplished, let him make a proper number of dependent openings for the discharge of them, and let him by bandage and other proper management keep the parts in constant contact with each other. and he will often find, that although he was foiled in his first intention of procuring immediate union, yet he will frequently succeed in this his second; he will yet save the scalp, shorten the cure, and prevent the great deformity arising (particularly to women) not only from the scar, but from the total loss of hair.

This union may often be procured, even though the cranium should have been perfectly denuded by the accident; and it is true, not only though it should have been stripped of its pericranium at first (see *Abernethy on the Injuries of the Head, case* 6), but even if that pericranium should have become sloughy and cast off, as Mr. Pott has often seen.

"Exfoliation from a cranium laid bare by external violence, and to which no other injury has been done than merely stripping it of its covering, is a circumstance (says Pott) which would not so often happen if it was not taken for granted that it must be, and the bone treated according to such expectation. The soft open texture of the bones of children and young people will frequently furnish an incarnation, which will cover their surface, and render exfoliation quite unnecessary (see also Brodie, in *Med. Chir. Trans. vol.* 14, *p.* 409): and even in those of mature age, and in whom the bones are still harder, exfoliation is full as often the effect of art as the intention of nature, and produced by a method of dressing calculated to accomplish such end, under a supposition of its being necessary. Sometimes, indeed, it happens that a small scale will necessarily separate, and the sore cannot be perfectly healed till such separation has been made; but this kind of exfoliation will be very small and thin in proportion to that produced by art, that is, that produced by dressing the surface of the bare bone with spirituous tinctures, &c.

Small wounds, that is, such as are made by instruments or bodies which pierce or puncture rather than cut, are in general more apt to become inflamed and to give trouble than those which are larger; and, in this part particularly, are sometimes attended with so high inflammation, and with such symptoms, as alarm both patient and surgeon.

If the wound affects the cellular membrane only, and has not reached the aponeurosis or pericranium, the inflammation and tumour affect the whole head and face, the skin of which wears a yellowish cast, and is sometimes thick set with small blisters, containing the same coloured serum: it receives the impression of the fingers, and becomes pale for a moment, but returns immediately to its inflamed colour; it is not very painful to the touch, and the eyelids and ears are always comprehended in the tumefaction, the former of which are sometimes so distended as to be closed; a feverish heat and thirst generally accompany it; the patient is restless, has a quick pulse, and most commonly a nausea and inclination to vomit.

This accident generally happens to persons of bilious habit, and is indeed an inflammation of the erysipelatous kind: it is somewhat alarming to look at, but is not often attended with danger. The wound does indeed neither look well, nor yield a kindly discharge, while the fever continues, but still it has nothing threatening in its appearance, none of that look which bespeaks internal mischief; the scalp continues to adhere firmly to the skull, and the patient does not complain of that tensive pain, nor is he afflicted with that fatiguing restlessness which generally attends mischief underneath the cranium.

Phlebotomy, lenient purges, and the use of the common febrifuge medicines, particularly those of the neutral kind, generally remove it in a short time. When the inflammation is gone off, it leaves on the skin for a little while a yellowish tint and a dry scurf, and, upon the disappearance of the disease, the wound immediately recovers a healthy aspect, and soon heals without any farther trouble. I do not believe that the exhibition of bark, in this form of erysipelas, is ever productive of any decided benefit.

Wounds and contusions of the head, which affect the brain and its membranes, are also subject to an erysipelatous kind of swelling and inflammation; but it is very different both in its character and consequences from the preceding.

In this (which is one of the effects of inflammation of the meninges), the febrile symptoms are much higher, the pulse harder and more frequent, the anxiety and restlessness extremely fatiguing, the pain in the head intense; and as this kind of appearance is, in these circumstances, most frequently the immediate precursor of matter forming between the skull and dura mater, it is generally attended with irregular shiverings, which are not followed by a critical sweat, nor afford any relief to the patient. To which it may be added, that in the former case the erysipelas generally appears within the first three or four days; whereas, in the latter, it seldom comes on till several days after the accident, when the symptomatic fever is got to some height. In the simple erysipelas, although the wound be crude and undigested, yet it has no other mark of mischief; the pericranium adheres firmly to the skull, and upon the cessation of the fever, all appearances become immediately favourable. In that which accompanies injury done to the parts underneath, the wound not only has a spongy, glassy, unhealthy aspect, but the pericranium in its neighbourhood separates spontaneously from the bone, and quits all cohesion with it. In short, one is an accident proceeding from a bilious habit, and not indicating any mischief beyond itself; the other is a symptom or a part of a disease, which is occasioned by injury done to the membranes of the brain: one portends little or no ill to the patient, and almost always ends well; the other implies great hazard, and most commonly ends fatally. It is therefore hardly necessary to say, that it behooves every practitioner to be careful in distinguishing them from each other.

If the wound be a small one, and *has passed through the cellular membrane to the aponeurosis and pericranium*, it is sometimes attended with very disagreeable, and even very alarming symptoms, but which arise from a different cause, and are very distinguishable from what has been yet mentioned.

In this, the inflamed scalp does not rise into that degree of tumefaction as in the erysipelas, neither does it pit, or retain the impression of the fingers of an examiner. It is of a deep red colour, unmixed with the yellow tint of the erysipelas; it appears tense, and is extremely painful to the touch: as it is not an affection of the cellular membrane, and as the ears and the eyelids are not covered by the parts in which the wound is inflicted, they are seldom if ever comprehended in the tumour, though they may partake of the general inflammation of the skin; it is generally attended with acute pain in the head, and such a degree of fever as prevents sleep, and sometimes brings on a delirium.

A patient in these circumstances will admit more free evacuations by phlebotomy than one labouring under an erysipelas: the use of warm fomentation is required in both, in order to keep the skin clean and perspirable, but an emollient cataplasm, which is generally forbid in the former, may in this latter case be used with great advantage.

When the symptoms are not very pressing, nor the habit very inflammable, this method will prove sufficient; but it sometimes happens that the scalp is so tense, the pain so great, and the symptomatic fever so high, that by waiting for the slow effect of such means, the patient runs a risk from the continuance of the fever, or else the injured aponeurosis and pericranium, becoming sloughy, produce an abscess, and render the case both tedious and troublesome. A division of the wounded part by a simple incision down to the bone, about half an inch or an inch in length, will most commonly remove all the bad symptoms, and, if it be done in time, will render every thing else unnecessary." We here perceive that, in this form of inflammation, the practice of making an incision had the sanction of Pott; but the extent of the wound recommended is moderate, and very different from what has been recently proposed for phlegmonous erysipelas of the limbs. With respect to the good effects of such an incision Desault considers them greatly exag-

gerated by authors; and while he admits that they are useful when the inflammation extends under the aponeurosis, he is not inclined to sanction it as a right proceeding in other instances.—(See *Œuvres Chir. par Bichat*, *t.* 2, *p.* 8.)

Thus Mr. Pott was of opinion, that the differences of the symptoms in the foregoing cases depended upon whether the wound only affected the skin and cellular membrane or reached more deeply to the aponeurosis and pericranium; a doctrine which has been justly regarded as questionable. With respect to the observation that in a puncture of the aponeurosis the swelling is confined within the limits of this fascia, and does not extend to the ears and eyelids, it is a sentiment which Desault thought arose rather from anatomical speculations than the observation of nature. The doctrine, indeed, must appear doubtful, when it is recollected, 1st, That the aponeurosis and pericranium are parts of scarcely any sensibility. 2dly, That the opinion had its origin at a period when these parts were imagined to be highly sensible. 3dly, That in other parts of the body, a wound in which a fascia or the periosteum is concerned is rarely attended with the above-described severe symptoms. 4thly, That here the wounds often affect only the skin and cellular membrane, and yet these symptoms occur even with a phlegmonous character. 5tly, On the contrary, in other instances, in which the aponeurosis and pericranium are undoubtedly wounded, no bad symptoms at all take place. 6thly, These symptoms may almost always be removed by the exhibition of tartarized antimony.—(*Œuvres Chir. de Desault*, *t.* 2, *p.* 8.) In the case often named inflammation of the fascia, after bleeding, it is not the fascia itself, which is the real and chief seat of the pain, inflammation, &c., but the subjacent cellular membrane and muscles. The theory of Desault is, that the erysipelatous affections of the scalp, so frequent after injuries of the head, are connected with disorder of the functions of the liver, produced by such accidents. Yet it is difficult to understand why a mere puncture of the scalp should cause this disorder of the liver more commonly than the same kind of wound of any other superficial part of the body.

The injuries to which the scalp is liable from contusion, or appearances produced in it by such general cause, may be divided into those in which the mischief is confined merely to the scalp, and those in which other parts are interested.

The former, which only come under our present consideration, are not indeed of importance, considered abstractedly. The tumour is either very readily dissipated, or the extravasated blood causing it is easily got rid of by a small opening. J. L. Petit first, and afterward Pott, particularly noticed this case, on account of an accidental circumstance which sometimes attends it, and renders it liable to be very much mistaken.

"When the scalp receives a very smart blow, it often happens that a quantity of extravasated blood immediately forms a tumour, easily distinguishable from all others, and generally very easily cured. But it also sometimes happens, that this kind of tumour produces to the fingers of an unadvised or inattentive examiner a sensation so like to that of a fracture, with depression of the cranium, as may be easily mistaken." Now if, upon such supposition, a surgeon immediately makes an incision into the tumid scalp, he may give his patient a great deal of unnecessary pain, and for that reason run some risk of his own character.

"The touch is in this case so liable to deception, that recourse should always be had to other circumstances and symptoms, before an opinion be given.

If a person with such tumour, occasioned by a blow, and attended with such appearances and feel, has any complaint which seems to be the effect of pressure made on the brain and nerves, or of any mischief done to the parts within the cranium, the division of the scalp, in order to inquire into the state of the skull, is right and necessary; but if there are no such general symptoms, and the patient is in every respect perfectly well, the mere feel of something like a fracture will not authorize or vindicate such operation, since it will often be found that such sensation is a deception, and that, when the extravasated fluid is removed, or dissipated, the cranium is perfectly sound and uninjured." —(*Pott.*)

With the exception of instances in which the dura mater suppurates from a blow on the head, and the symptoms are such as to require the trephine, or other examples in which an abscess forms under the scalp, or a large quantity of blood is effused in the same situation, none of the cases which have here been considered can justify making incisions in the scalp When blood is extravasated under the scalp, the surgeon need not be too officious with his knife, merely because there is a tumour containing blood. The facility with which an effusion of blood under the scalp is dispersed is well illustrated in a case mentioned by Mr. Brodie. He was consulted about a young gentleman, under whose scalp an effusion of blood extended from the supercilliary ridges to the nape of the neck, and from ear to ear. The blood appeared to be in a fluid state, and was so copious, that no part of the cranium could be felt. In a few weeks, and with the aid of a cold lotion, the whole tumour was dispersed. Mr. Brodie observes, that whatever might be the vessel ruptured, it must have continued to bleed a considerable time, in order to produce so large an extravasation. I have seen three or four cases nearly as remarkable as the preceding, and having a similar favourable termination under the use of simple discutient lotions and occasional purgatives. In one instance, attended by Mr. Brodie, he succeeded in preventing the effusion from attaining the extent described in his other case, by means of pressure applied to the point where the blow had been received, and a vessel ruptured.—(See *Med. Chir. Trans. vol.* 15, *p.* 406.)

The utility of an incision in what was supposed by Pott to be an inflammation of the aponeurosis is at least questionable, as far as it is done under the idea of merely obviating tension, without there being any matter to be discharged. Incisions, expressly for the purpose of exposing the bone, are only right as a preparatory step to trephining, when the necessity for this operation is indicated by decided and urgent symptoms of pressure on the brain. Now such pressure, in any of the examples above treated of, can only arise from a suppuration under the skull, a subject which will presently be considered.

Dr. Hennen, in his truly practical work, has very properly advised surgeons not to be content with clipping away a little of the hair around the injury, but always to have the head shaved to a proper extent. This proceeding, which is perfectly harmless in itself, is more generally right than the custom of cutting the scalp, which has been too frequently employed without any rational aim. The free removal of the hair directly after the accident often brings into view marks indicative of other parts of the head having been struck besides that which is at first noticed, and thus the practitioner will have a more correct notion of the serious nature of the accident than he might otherwise have conceived, and be more strict in his mode of treatment. Nay, fractures and depression of the skull, sometimes not denoted by any disturbance of the functions of the brain, and liable to escape observation while concealed under the hair, are frequently detected after its removal, and the surgeon being now aware of the extent and situation of the mischief, must of course be better qualified to conduct the treatment. In short, as Dr. Hennen has observed, "independent of the more accurate view (thus procured), we facilitate the application of leeches, if they may be found necessary, and of a most excellent adjuvant on all occasions, viz., cold applications."

It affords me particular pleasure to be able to number so good a surgeon as Dr. Hennen among the advocates of Schmucker's plan of having the head well shaved and covered with cloths wet with a very cold lotion; a practice which the latter eminent surgeon always adopted, whether a sabre-cut or gun-shot injury of this part had the appearance of being serious or not. "As soon as the patient was brought to the hospital with a wound of the head, whether the injury looked important or not (says Schmucker), I directed the hair to be immediately removed, and after the necessary dilatation applied dressings. Sixteen ounces of blood were next taken away, and the evacuation, in less quantity, repeated, according to circumstances, three or four times within the space of twenty-four hours. The pulse now generally became softer, and the determination of blood to the head lessened. Over the dressings and the whole of the head, thick cloths, dipped in the cold mixture hereafter specified, were laid, and renewed

every hour These cloths were kept in their place with the bandage called the grand couvre-chef.—(See *Bandage.*) As internal medicines, the nitrate of potassa, neutral salts, and emollient and stimulating clysters, and gentle aperients were given. These means were employed, both in slight injuries and in those where the bones were depressed, and the fissures and fractures were accompanied with violent convulsive twitchings, coma, paralysis, and other bad symptoms; and even in cases where the use of the trephine was indispensable, the practice was continued until the cure was complete." Schmucker assures us, that under such treatment, fewer patients with wounds of the head were lost than used previously to happen, especially of those whose injuries at first had the appearance of being but slight. —(See *Chir. Wahrnehmungen, b.* 1, *p.* 154.)

Schmucker was led to try this practice by the great benefit which he had seen afforded by the application of cold water to the head in cases of mania, attended with great determination of blood to the brain. And in order to increase the efficacy of the water, he added to every five gallons of it two quarts of vinegar, sixteen ounces of nitre, and eight of the muriate of ammonia. This mixture was then preserved for use in a cold place.—(*Vol. cit. p.* 153.) Or, in order to avail ourselves fully of the frigorific effects of this mixture, it should be prepared, as Dr. Hennen observes, in small quantities, and used immediately before its temperature has risen; or "snow, or pounded ice, or ice-water applied to the parts in a half filled bladder, or cloths simply dipped in cold water, will often answer every purpose.—(*On Military Surgery, p.* 279, *ed.* 2.) Dr. Hennen mentions one important fact, in recommendation of cold applications, antimonials, and saline purgatives, preceded by the common blue pill, and assisted with quiet and abstinence, viz. by such means, "those troublesome puffy enlargements and erysipelatous affections of the scalp, which so often succeed to bruises, are prevented, and where the evacuant plan is duly observed, the extensive and formidable erysipelatous affections, so common formerly, are rare and mild at present in military hospitals."

2. *Effects of Contusion on the Dura Mater and Parts within the Skull.*

In consequence of blows, falls, and other shocks, either blood may be effused under the cranium, or inflammation and suppuration of the dura mater may arise. The best description of the latter case is that delivered by Mr. Pott.

Smart and severe strokes on the middle part of the bones, at a distance from the sutures, he says, are most frequently followed by this kind of mischief: the coats of the small vessels, which sustain the injury, inflame and become sloughy, and in consequence of such alteration in them, the pericranium separates from the outside of that part of the bone which received the blow, and the dura mater from the inside, the latter of which membranes, soon after such inflammation, becomes sloughy also, and furnishes matter, which matter being collected between the said membrane and the cranium, and having no natural outlet, whereby to escape or be discharged, brings on a train of very terrible symptoms, and is a very frequent cause of destruction. The effect of this kind of violence is frequently confined to the vessels connecting the dura mater to the cranium, in which case the matter is external to the said membrane; but sometimes the matter formed in consequence of such violence is found on the surface of the brain, or between the pia and dura mater, as well as on the surface of the latter; or, perhaps, in all these three situations at the same time.

The difference of this kind of disease from either an extravasation of blood or a concussion of the brain is great and obvious. "All the complaints produced by extravasation are such as proceed from pressure made on the brain and nerves, and obstruction to the circulation of the blood through the former; stupidity, loss of sense and voluntary motion, laborious and obstructed pulse and respiration, &c., and (which is of importance to remark), *if the effusion be at all considerable, these symptoms appear immediately or very soon after the accident.*

The symptoms attending an inflamed or sloughy state of the membranes, in consequence of external violence, are very different; they are all of the febrile kind, and never at first imply any unnatural pressure: such are pain in the head, restlessness, want of sleep, frequent and hard pulse, hot and dry skin, flushed countenance, inflamed eyes, nausea, vomiting, rigor; and, towards the end, convulsion and delirium. And *none of these appear at first, that is, immediately after the accident; seldom until some days are passed.*"

This last observation, made by Pott, is one that is well worthy of the practitioner's constant recollection, lest he wrongly fancy his patient secure too soon, and neglect the early use of the only means by which a recovery can be effected. Thus, as Sir Astley Cooper notices, the time when inflammation of the brain (and, it may be added, of its membranes) follows the violence is generally about a week; rarely sooner. Frequently it does not come on till a fortnight or three weeks after the injury; and even more time must elapse before the patient is quite safe, or ought to deviate from a strict and temperate regimen. In confirmation of this remark, a case is mentioned, where the neglect to keep the bowels regular brought on a fatal attack of inflammation of the brain, as late as four months after the receipt of a blow on the head.—(*Lectures, &c. p.* 339.)

One set or class of symptoms is produced by an extravasated fluid making pressure on the brain and origin of the nerves, so as to impair or abolish voluntary motion and the senses; the other is caused by the inflamed or putrid state of the membranes covering the brain, and seldom affects the organs of sense, until the latter end of the disease, that is, until a considerable quantity of matter is formed, which matter must press like any other fluid.

"If there be neither fissure nor fracture of the skull, nor extravasation nor commotion underneath it, and the scalp be neither considerably bruised nor wounded, the mischief is seldom discovered or attended to for some few days. The first attack is generally by pain in the part which received the blow. This pain, though beginning in that point, is soon extended all over the head, and is attended with a languor, or dejection of strength and spirits, which are soon followed by a nausea and inclination to vomit, a vertigo or giddiness, a quick and hard pulse, and an incapacity of sleeping, at least quietly. A day or two after this attack, if no means preventive of inflammation are used, the part stricken generally swells, and becomes puffy and tender, but not painful; neither does the tumour arise to any considerable height, nor spread to any great extent: if this tumid part of the scalp be now divided the pericranium will be found of a darkish hue; and either quite detached or very easily separable from the skull, between which and it will be found a small quantity of dark-coloured ichor.

If the disorder has made such progress that the pericranium is quite separated and detached from the skull, the latter will even now be found to be somewhat altered in colour from a sound, healthy bone.

From this time the symptoms generally advance more hastily and more apparently; the fever increases, the skin becomes hotter, the pulse quicker and harder, the sleep more disturbed, the anxiety and restlessness more fatiguing; and to these are generally added irregular rigors, which are not followed by any critical sweat, and which, instead of relieving the patient, add considerably to his sufferings. If the scalp has not been divided or removed, until the symptoms are thus far advanced, the alteration of the colour of the bone will be found to be more remarkable; it will be found to be whiter and more dry than a healthy one; or, as Fallopius has very justly observed, it will be found to be more like a dead bone: the sanies or fluid between it and the pericranium will also, in this state, be found to be more in quantity, and the said membrane will have a more livid, diseased aspect.

In this state of matters, if the dura mater be denuded it will be found to be detached from the inside of the cranium, to have lost its bright silver hue, and to be, as it were, smeared over with a kind of mucus, or with matter, but not with blood. Every hour after this period, all the symptoms are exasperated, and advance with hasty strides: the headache and thirst become more intense, the strength decreases, the rigors are more frequent, and at last convulsive motions, attended in some with delirium, in others with paralysis or comatose stupidity, finish the tragedy.

If the scalp has not been divided till this point of time, and it be done now, a very offensive discoloured kind of fluid will be found lying on the bare cranium

whose appearance will be still more unlike to the healthy natural one; if the bone be now perforated, matter will be found between it and the dura mater, generally in considerable quantity, but different in different cases and circumstances. Sometimes it will be in great abundance, and diffused over a very large part of the membrane; and sometimes the quantity will be less, and consequently the space which it occupies smaller. Sometimes it lies only on the exterior surface of the dura mater; and sometimes it is between it and the pia mater, or also even on the surface of the brain, or within the substance of it, &c.

As the inflammation and separation of the dura mater is not an *immediate* consequence of the violence, so neither are the symptoms immediate, seldom until some days have passed; the fever at first is slight, but increases gradually; as the membrane becomes more and more diseased, all the febrile symptoms are heightened; the formation of matter occasions rigors, frequent and irregular, until such a quantity is collected as brings on delirium, spasm, and death."

When the scalp has been wounded, Mr. Pott observes, the wound will for some little time have the same appearance as a mere simple wound of this part, unattended with other mischief, would have; it will, like that, at first discharge a thin sanies or gleet, and then begin to suppurate; it will digest, begin to incarn, and look perfectly well; but after a few days, all these favourable appearances will vanish; the sore will lose its florid complexion and granulated surface; will become pale, glassy, and flabby; instead of good matter, it will discharge only a thin discoloured sanies; the lint with which it is dressed, instead of coming off easily (as in a kindly suppurating sore), will stick to all parts of it; and the pericranium, instead of adhering firmly to the bone, will separate from it all round to some distance from the edges.

"This alteration in the face and circumstances of the sore is produced merely by the diseased state of the parts underneath the skull; which is a circumstance of great importance in support of the doctrine advanced; and is demonstrably proved, by observing that this diseased aspect of the sore and this spontaneous separation of the pericranium are always confined to that part which covers the altered or injured portion of the dura mater, and do not at all affect the rest of the scalp: nay, if it has by accident been wounded in any other part, or a portion has been removed from any part where no injury has been done to the dura mater, no such separation will happen, the detachment above will always correspond to that below, and be found no where else.

The first appearance of alteration in the wound immediately succeeds the febrile attack; and as the febrile symptoms increase, the sore becomes worse and worse; that is, degenerates more and more from a healthy, kindly aspect.

Through the whole time from the first attack of the fever to the last and fatal period, an attentive observer will remark the gradual alteration of the colour of the bone, if it be bare. At first, it will be found to be whiter and more dry than the natural one; and as the symptoms increase, and either matter is collected or the dura mater becomes sloughy, the bone inclines more and more to a kind of purulent hue or whitish yellow: and it may also be worth while in this place to remark, that if the blow was on or very near to a suture, and the subject young, the said suture will often separate in such a manner as to let through it a loose, painful, ill-natured fungus; at which time, also, it is not uncommon for the patient's head and face to be attacked with an erysipelas.

In those cases in which the scalp is very little injured by the bruise, and in which there is no wound nor any immediate alarming symptoms or appearances, the patient feels little or no inconvenience, and seldom makes any complaint, until some few days are past. At the end of this uncertain time, he is generally attacked by the symptoms already recited; these are not pressing at first, but they soon increase to such a degree, as to baffle all our art: from whence it will appear, that when this is the case, the patient frequently suffers from what seems at first to indicate his safety, and prevents such attempts being made, and such care from being taken of him, as might prove preventive of mischief.

But if the integuments are so injured as to excite or claim our early regard, very useful information may from thence be collected; for whether the scalp be considerably bruised, or whether it be found necessary to divide it for the discharge of extravasated blood, or on account of worse appearances or more urgent symptoms, the state of the pericranium may be thereby sooner and more certainly known: if in the place of such bruise, the pericranium be found spontaneously detached from the skull, having a quantity of discoloured sanies between them under the tumid part, in the manner already mentioned, it may be regarded as a pretty certain indication, either that the dura mater is beginning to separate in the same manner, or that, if some preventive means be not immediately used, it will soon suffer; that is, it will inflame, separate from the skull and give room for a collection of matter between them And with regard to the wound itself, whether it was made at the time of the accident, or afterward artificially, it is the same thing; if the alteration of its appearance be as related, if the edges of it spontaneously quit their adhesion to the bone, and the febrile symptoms are at the same time making their attack, these circumstances will serve to convey the same information, and to prove the same thing.

The particular effect of contusion is frequently found to attend on fissures, and undepressed fractures of the cranium, as well as on extravasations of fluid, in cases where the bone is entire; and, on the other hand, all these do often happen without the concurrence of this individual mischief. All this is matter of accident: but let the other circumstances be what they may, the spontaneous separation of the altered pericranium, in consequence of a severe blow, is almost always followed by a suppuration between the cranium and dura mater; a circumstance extremely well worth attending to in fissures and undepressed fractures of the skull, because it is from this circumstance principally that the bad symptoms and the hazard in such cases arise.

It is no very uncommon thing for a smart blow on the head to produce some immediate bad symptoms, which after a short space of time disappear and leave the patient perfectly well. A slight pain in the head, a little acceleration of pulse, a vertigo and sickness, sometimes immediately follow such accident, but do not continue many hours, especially if any evacuation has been used. These are not improbably owing to a light commotion of the brain, which having suffered no material injury thereby, soon cease. But if, after an interval of some time, the same symptoms are renewed; if the patient, having been well, becomes again feverish and restless, and that without any new cause; if he complains of being languid and uneasy, sleeps disturbedly, loses his appetite, has a hot skin, a hard, quick pulse, and a flushed, heated countenance; and neither irregularity of diet nor accidental cold has been productive of these; the mischief is most certainly impending, and that most probably under the skull.

If the symptoms of pressure, such as stupidity, loss of sense, voluntary motion, &c., appear some few days after the head has suffered injury from external mischief, they do most probably imply an effusion of a fluid somewhere; this effusion may be in the substance of the brain, in its ventricles, between its membranes, or on the surface of the dura mater; and which of these is the real situation of such extravasation is a matter of great uncertainty, none of them being attended with any peculiar mark or sign that can be depended upon as pointing it out precisely; but the inflammation of the dura mater, and the formation of matter between it and the skull, in consequence of contusion, is generally indicated and preceded by one which Mr. Pott has hardly ever known to fail; *a puffy, circumscribed, indolent tumour of the scalp, and a spontaneous separation of the pericranium from the skull under such tumour.*

These appearances, therefore, following a smart blow on the head, and attended with languor, pain, restlessness, watching, quick pulse, headache, and slight, irregular shiverings, do almost infallibly indicate an inflamed dura mater, and pus either forming or formed between it and the cranium."

By detachment of the pericranium is not meant every separation of it from the bone which it should cover. It may be, and often is, cut, torn, or scraped off, without any such consequence; but these separations are violent; whereas that which Mr. Pott means is spontaneous, and is produced by the destruction of those vessels by which it was connected with the skull, and by which the communication between it and

the internal parts was carried on; and therefore it is to be observed, that it is not the mere removal of that membrane which causes the bad symptoms, but it is the inflammation of the dura mater; of which inflammation this spontaneous secession of the pericranium is an almost certain indication.

Sometimes the scalp is so wounded at the time of the accident, or so torn away, as to leave the bone perfectly bare; and yet the violence has not been such as to produce the evil just now spoken of. In this case, if the pericranium be only turned back along with the detached portion of scalp, there may be probability of its reunion; and it should therefore be immediately made clean and replaced, for the purpose of such experiment; which, if it succeeds, will save time and prevent considerable deformity. Should the attempt fail, it can only be in consequence of the detached part sloughing. Hence, removing it with a knife, though allowed by Pott, is now never practised. Frequently, when the scalp does not adhere at once, it becomes attached to the cranium afterward by a granulating process. When the detached piece sloughs, the worst that can happen is an exfoliation from the bare skull.

Sometimes the force which detaches or removes the scalp also occasions the mischief in question; but, the integuments being wounded or removed, we cannot have the criterion of the tumour of the scalp for the direction of our judgment. Our whole attention must be directed to the wound and general symptoms. The edges of the former will digest as well, and look as kindly for a few days, as if no mischief was done underneath. But after some little space of time, when the patient begins to be restless and hot, and to complain of pain in the head, these edges will lose their vermilion hue, and become pale and flabby. Instead of matter, they will discharge a thin gleet, and the pericranium will loosen from the skull to some distance from the said edges. Immediately after this, all the general symptoms are increased and exasperated; and as the inflammation of the membrane is heightened or extended, they become daily worse and worse, until a quantity of matter is formed and collected, and brings on that fatal period, which, though uncertain as to date, very seldom fails to arrive.

"The method of attempting the relief of this kind of injury consists in two points: viz. *to endeavour to prevent the inflammation of the dura mater;* or, that being neglected or found impracticable, *to give discharge to the fluid collected within the cranium, in consequence of such inflammation.*

Of all the remedies in the power of art, for inflammations of membranous parts, there is none equal to phlebotomy. To this truth many diseases bear testimony; pleurisies, ophthalmies, strangulated hernias, &c.; and if any thing can particularly contribute to the prevention of the ills likely to follow severe contusions of the head, it is this kind of evacuation; but then it must be made use of in such a manner as to become truly a preventive; that is, it must be made use of immediately and freely."

Acceleration or hardness of pulse, restlessness, anxiety, and any degree of fever, after a smart blow on the head, are always to be suspected and attended to. Immediate, plentiful, and repeated evacuations by bleeding have in many instances removed these in persons to whom Mr. Pott firmly believes very terrible mischief would have happened, had not such precaution been used. In this, as well as some other parts of practice, we neither have nor can have any other method of judging, than by comparing together cases apparently similar. Mr. Pott had more than once or twice seen that increased velocity and hardness of pulse, and that oppressive languor, which most frequently precede mischief under the bone, removed by free and repeated bloodletting; and had often, much too often, seen cases end fatally, whose beginnings were fully as slight, but in which such evacuation had been either neglected or not complied with. This judicious writer, "would by no means be thought to infer from hence, that early bleeding will always prove a certain preservative; and that they only die to whom it has not been applied: this, like all other human means, is fallible; and perhaps there are more cases out of its reach than within it, but where preventive means can take place, this is certainly the best and the most frequently successful.

The second intention, viz. *the discharge of matter collected under the cranium*, can be answered only by the perforation of it.

When from the symptoms and appearances already described, there is just reason for supposing matter to be formed under the skull, the operation of perforation cannot be performed too soon: it seldom happens that it is done soon enough."

In short, whenever the dura mater, after the head has received external violence, separates or is detached spontaneously from the bone underneath it, and such separation is attended with the collection of a small quantity of thin brown ichor, an alteration of colour in the separated pericranium, unnatural dryness of the bone, chilliness, horripilatio, languor, and some degree of fever, Mr. Pott considers the operation indispensably necessary to save the patient's life.

When the skull has been once perforated, and the dura mater thereby laid bare, the state of the matter must principally determine the surgeon's future conduct. In some cases, one opening will prove sufficient for all necessary purposes; in others, several may be necessary

Notwithstanding the operation of perforation be absolutely and unavoidably necessary, as Mr. Pott remarks, "the repetition of bloodletting or cooling laxative medicines, the use of antiphlogistic remedies, and a most strict observance of a low diet and regimen, are as indispensably requisite after such operation as before: the perforation sets the membrane free from pressure, and gives vent to collected matter, but nothing more; the inflamed state of the parts under the skull, and all the necessary consequences of such inflammation, call for all our attention, full as much afterward as before; and although the patient must have perished without the use of the trephine, yet the merely having used it will not preserve him without every other caution and care."—(*Pott.*)

In relation to this subject, a remark made by Sir Astley Cooper merits notice: when pus lies between the dura mater and skull, the application of the trephine, he acknowledges, is a successful practice; but, according to his experience, this situation of the purulent matter is comparatively rare, as it generally collects between the pia mater and surface of the brain, *for which case an operation will be useless.*—(*Lectures, &c. vol.* 1, *p.* 325.) It is stated by Mr. Brodie, that in hospital practice, suppuration between the dura mater and the bone, in consequence of fracture, is also less common at the present period than when Mr. Pott wrote; a change which he refers to the stricter antiphlogistic plan adopted by modern surgeons, whether the early symptoms be or be not of a dangerous description.—(See *Med. Chir. Trans. vol.* 14, *p.* 411.)

I think it not improper to recommend again the practice of applying cold wet cloths to the head for the prevention and relief of inflammation of the dura mater; a plan to which, as already explained, Schmucker ascribed a good deal of the success with which he treated injuries of the head. It is favourably mentioned by Dr. Hennen, and has received the recommendation of another modern writer, whose opinion must have great weight: "In the inflammation which succeeds slowly to injuries of the head, a species of inflammation not more insidious in its approach than dangerous in its consequences, cold is by far the most efficacious remedy that has yet been discovered."—(See *Thomson's Lectures on Inflammation*, *p.* 181.)

Both tables of the skull sometimes exfoliate in consequence of external violence. The dead bone must be removed, as soon as loose; and, if necessary, the scalp divided for the purpose.

3. *Fissures and Fractures of the Cranium, without Depression.*

Fractures of the cranium are divisible into "those in which the broken parts keep their proper level or equality of surface with the rest of the skull, and those in which they do not; or in other words, fractures without depression and fractures with.

These two distinctions are all which are really necessary to be made, and will be found to comprehend every violent division of the parts of the skull (not made by a cutting instrument), from the finest capillary fissure, up to the most complicated fracture."—(*Pott.*) In most instances, the fracture takes place in the upper part of the cranium; and it is also correctly noticed by Mr. Brodie, that fractures of its basis are always the consequence of very great violence, and re

coveries from them comparatively rare.—(*Med. Chir. Trans. vol.* 14, *p.* 328.) Sometimes the fracture does not occur at the point to which the violence has been directly applied, but elsewhere, as the effect of what the French term a *contre-coup*. Various explanations of the fact have been offered. Mr. Earle has never known it happen, except when the occiput seemed to have been forcibly impelled against the atlas.—(*Brodie, in Med. Chir. Trans. vol.* 14, *p.* 329.) An ingenious attempt to account for the circumstance may be found in the writings of Mr. C. Bell; though certain cases on record will not conform to any principles yet offered in explanation of them. The disjunction of the sutures is much more rare than fractures of the cranium, and can only happen in young subjects, in whom the sutures are not yet consolidated. They are accidents implying the operation of great violence, and in this point of view may be viewed as dangerous.—(See *Brodie, in Med. Chir. Trans. vol.* 14, *p.* 332.)

No truth in surgery is now better understood and established, than that the bad symptoms very frequently accompanying a broken skull are not produced by the breach made in the bone, nor indicate such breach to have been made. As Sir Astley Cooper remarks, the danger of fractures of the skull depends upon their being united with concussion or extravasation; there is also a remote danger from inflammation.—(*Lectures, &c. p.* 289.) This was the doctrine so well explained by Pott, who observes "the sickness, giddiness, vomiting, and loss of sense and motion can only be the consequence of an affection of the brain, as the common sensorium. They may be produced by its having been violently shaken, by a derangement of its medullary structure, or by unnatural pressure made by a fluid extravasated on its surface, or within its ventricles; but never can be caused by the mere division of the bone (considered abstractedly); which division, in a simple fracture, can neither press on nor derange the structure of the parts within the cranium.

If the solution of continuity in the bone be either produced by such a degree of violence as hath caused a considerable disturbance in the medullary parts of the brain, or has disturbed any of the functions of the nerves going off from it; or has occasioned a breach of any vessel or vessels, whether sanguine or lymphatic, and that hath been followed by an extravasation or lodgement of fluid; the symptoms necessarily consequent upon such derangement, or such pressure, will follow: but they do not follow because the bone is broken; their causes are superadded to the fracture, and although produced by the same external violence, are yet perfectly and absolutely independent of it; so much so that they are frequently found where no fracture is.

The operation of the trepan is frequently performed in the case of simple fractures, and that very judiciously and properly; but it is not performed because the bone is broken or cracked. A mere fracture or fissure of the skull can never require perforation, or that the dura mater under it be laid bare; the reason for doing this springs from other causes than the fracture, and those really independent of it: they spring from the nature of the mischief which the parts within the cranium have sustained, and not from the accidental division of the bone. From these arise the threatening symptoms; from these all the hazard; and from these the necessity and vindication of performing the operation of the trepan.

If a simple fracture of the cranium was unattended in present with any of the before-mentioned symptoms, and there was no reason for apprehending any other evil in future, that is, if the solution of continuity in the bone was the whole disease, it could not possibly indicate any other curative intention but the general one in all fractures, viz. the union of the divided parts." Even fractures of the basis of the skull, which are most frequently fatal, prove so, not because this part of the cranium is broken (the fracture itself being here not more dangerous than elsewhere), but "because it is almost invariably complicated with extensive injury of other and more important parts."—(*Brodie, in Med. Chir. Trans. vol.* 14, *p.* 328.) The post mortem examinations which I have attended, lead me to believe that most of these cases are complicated with extravasation.

I could relate numerous examples to the point, if it were any longer necessary, in the present state of surgical knowledge, to cite facts in proof of the important truth, that the mere undepressed fissure or fracture of the skull itself cannot be the source of the immediate bad symptoms, but that in these cases the whole of the sudden peril arises from the manner in which the brain and its membranes have been hurt by the same violence which caused the injury of the bone. Professor Thomson had opportunities of witnessing in the Netherlands several instances, which can leave no doubt upon this subject. "In some of the wounds (says he) in which the head had been struck obliquely by the sabre, portions of the cranium had been removed, without the brain appearing to have sustained much injury. In one case of this kind, where a considerable portion of the upper part of the occipital bone, *along with the dura mater*, had been removed, a tendency to protrusion of the brain took place during an attack of inflammation; a slight degree of stupor with loss of memory occurred; but on the inflammatory state having been subdued, the brain sunk to its former level, the stupor went off, and the memory returned:"—and in another remarkable sabre-cut, more than an inch in breadth of the left lobe of the cerebellum was exposed, and *was seen pulsating for a period of eight weeks*, yet the injury was unaccompanied with any particular constitutional symptoms.—(See *Obs. made in the Military Hospitals of Belgium, p.* 50, 51.)

In many cases of simple undepressed fractures of the cranium, it is true that trephining is necessary; but the reasons for the operation in these instances are, first, the immediate relief of present symptoms, arising from the pressure of extravasated fluid; and, secondly, the discharge of matter, formed between the skull and dura mater, in consequence of inflammation. The operation of trephining was also recommended by Pott, as a *preventive* of ill consequences; a practice, however, which is now never adopted; and many writers of the highest reputation, especially Desault, Dease, Mr. John Bell, and Mr. Abernethy, have strongly remonstrated against it.

The latter remarks, "In the accounts which we have of the former practice in France, it is related, that surgeons made numerous perforations along the whole track of a fracture of the cranium; and, as far as I am able to judge, without any clear design. Mr. Pott also advises such an operation, with a view to prevent the inflammation and suppuration of the dura mater, which he so much apprehended. But many cases have occurred of late, where, even in fractures with depression, the patients have done well without an operation."

Mr. Abernethy next relates several cases of fracture of the cranium with depression, which terminated favourably, although no operation was performed. This judicious surgeon thinks that these cases, as well as a great many others on record, prove that at all events a slight degree of pressure may not derange the functions of the brain, for a limited time after its application, and in this circumstance probably never; for all those patients whom he had an opportunity of knowing for any length of time after the accident, continued as well as if nothing of the kind had happened to them. In Mr. Hill's *Cases in Surgery*, two instances of this sort are related, and Mr. Hill knew both the patients for many years afterward: yet no inconvenience arose. Indeed, it is not easy to conceive that the pressure, which caused no ill effects at a time when the contents of the cranium filled its cavity completely, should afterward prove injurious, when they have adapted themselves to its altered size and shape. Severe illness, it is true, often intervenes between the receipt of the injury, and the time of its recovery; and many surgeons might be inclined to attribute this to pressure; but it equally occurs when the depressed portion is elevated. If a surgeon, prepossessed with the opinion that elevation of the bone is necessary in every instance of depressed cranium, should have acted upon this opinion in several of the cases which Mr. Abernethy has related, and afterward have employed proper evacuations, his patients would probably have had no bad symptoms, and he would naturally have attributed their well-doing to the mode of treatment which he had pursued: yet these cases did equally well without an operation.—(See *Abernethy's Surgical Works, vol.* 2, *p.* 4, *&c.* 8vo. *Lond.* 1811.)

Depressed fractures of the skull not being our immediate consideration, we need not expatiate upon them; but it seemed right to make the preceding remarks, in order to show how unnecessary it must be to trephine a patient, merely because there is a fracture in the cranium, and with a view of *preventing* bad consequences. Even when the fracture is depressed, it is not neces-

sary, unless there are evident signs that the degree of pressure thus produced on the brain is the cause of existing bad symptoms.

The inflammation and suppuration of the parts beneath the skull, which Mr. Pott wished so much to prevent by trephining early, do not arise from the occurrence of a breach in the cranium, but are the consequences of the same violence which was the occasion of the fracture. Hence it is obvious, that removing a portion of the bone cannot in the least prevent the inflammation and suppuration, which must result from the external violence which was first applied to the head; but, on the contrary, such a removal, being an additional violence, must have a tendency to increase the inevitable inflammatory mischief.

From what has been said, it is not to be inferred, however, that trephining is never proper, when there is a simple undepressed fracture of the skull. Such injury may be joined with an extravasation of blood on the dura mater; or it may be followed by the formation of matter between this membrane and the cranium; in both which circumstances, the operation is essential to the preservation of the patient, immediately, but not before the symptoms indicative of the existence of dangerous pressure on the brain begin to show themselves. —(See *Trephine.*)

A fracture of the skull, unattended with urgent symptoms, and not brought into the surgeon's view by any accidental wound of the integuments, often remains for ever undiscovered; and as no benefit could arise from laying it bare by an incision, such practice should never be adopted. The surgeon ought only to be officious in this way, when he can accomplish by it some better object than the mere gratification of his own curiosity. And as we shall find from the perusal of this article, and the one entitled *Trephine*, that in these cases, the removal of pressure off the surface of the brain is the only possible reason for ever perforating the cranium with this instrument; and as dividing the scalp is only a useful measure when it is preparatory to such operation; neither the one nor the other should ever be practised, unless there exist unequivocal symptoms that there is a dangerous degree of pressure operating on the brain, and caused either by matter, extravasated blood, or a depressed portion of the skull. If any exceptions can be made to this observation, these are cases in which it is advisable to remove loose splinters and fragments of bone, or balls, plainly felt under the scalp.

The true mode of *preventing* the bad effects, frequently following, but not arising from, simple fractures of the skull, is not to trephine, but to put in practice all kinds of antiphlogistic means. For this purpose, let the patient be repeatedly and copiously bled, both from the arm and temporal arteries; let him be properly purged; give him antimonials; keep him on the lowest diet; let him remain in the most quiet situation possible; and if, notwithstanding such steps, the symptoms of inflammation of the brain continue to increase, let a large blister be applied to the scalp. If the scalp be wounded, it is to be healed as speedily as possible. Bloodletting and purgatives (as Sir Astley Cooper remarks) will sometimes remove the symptoms of concussion and extravasation, when they accompany the fracture, and a few hours will often show that the trephine, which was at first thought indispensable, is unnecessary. Irreparable mischief might arise from your making an incision, and converting a simple into a compound fracture. "If you act prudently (he adds), you will try bleeding and purgatives before you operate; and the depletion will prove of the greatest possible advantage in preventing inflammation."—(*Lectures, vol.* 1, *p* 296.) These are the cases, also, in which the topical application of cold water to the shaved and naked head, by means of cloths kept constantly wet, is an eligible, though in this country a much-neglected practice. Numerous instances, however, in favour of the method are recorded by the experienced Schmucker (*Chir. Wahrnehmungen, b.* 1, *Berlin*, 1774), and the trials which I have seen made of it, give me a high opinion of its superior efficacy. When, in spite of all these measures, matter forms under the cranium, attended with symptoms of pressure, a puffy tumour of the injured part of the scalp, or those changes of the wound, if there is one, which Mr. Pott has so excellently described; not a moment should be lost in delaying to perforate the bone with the trephine, and giving vent to the confined matter.

Experience teaches that fractures at the basis of the skull are extremely dangerous, because they are generally attended with extravasation, or followed by inflammation of the brain, in consequence of the violence of the injury. According to Sir Astley Cooper, they are produced by falls from a great height on the summit of the head. The whole weight of the body is received on the foramen magnum, and cuneiform process of the os occipitis, and, in many instances, the consequence is a transverse fracture through the foramen magnum, the cuneiform process, and part of the temporal bone. A discharge of blood into each meatus auditorius accompanies the accident. It is supposed, also, that the deafness, which sometimes remains during life, in rare instances of recovery, is the result of this kind of injury. —(*Lectures, &c. vol.* 1, *p.* 289.)

A fracture within the orbit is sometimes occasioned by the forcible introduction of a stick, weapon, or pointed instrument, and is generally a fatal case, from the pressure and irritation of the depressed splinters of bone, and the simultaneous wound of the brain. The symptoms in the beginning, however, are frequently mild and deceitful, and it is not till inflammation and suppuration ensue, that the patient's condition is always such as to create immediate alarm. A case, exemplifying this fact, is reported by Sir A. Cooper. —(*Vol. cit. p.* 295.) The same eminent surgeon mentions the occasional production of a circular fracture of the entire cranium, by a blow on the vertex; also the emphysema of the forehead, or the escape of the air, if there be a wound, caused when the nose is blown, in the case of a fracture extending into the frontal sinuses; the complete detachment, sometimes met with, of the fragments, instead of their depression. His observations confirm the fact, that fractures of the skull, if unaccompanied with concussion or compression, become united like those of other bones; but, he adds, that it is more slowly, and that where the interspace is wide, it will not be filled up with bony matter.—(*P.* 297, 298.)

4. *Fractures of the Cranium with Depression.*

In simple fractures of the skull, or those in which the parts of the broken bone are not depressed from their situation, Mr. Pott remarks, that "the chirurgical intention and requisite treatment are the same in each, viz. to procure a discharge for any fluid which may be extravasated in present (*provided the pressure of such extravasation produces urgent symptoms, a condition which should here be added*), and to guard against the formation or confinement of matter." The prevention of suppuration will, as we have already remarked, be best accomplished, not by perforating the cranium, as Mr. Pott advised, but by copious bleeding, evacuations, cold washes to the head, blisters, and a rigorous antiphlogistic regimen. However, the confinement of matter, producing symptoms of pressure on the brain, certainly indicates the immediate use of the trephine.

"But (says the author) in fractures attended with depression there are other intentions. In these the depressed parts are to be elevated, and such as are so separated as to be incapable of reunion, or of being brought to lie properly, and without pressing on the brain, are to be totally removed. These circumstances are peculiar to a depressed fracture; but although they are peculiar, they must not be considered as sole, but as additional to those which have been mentioned at large under the head of simple fracture; commotion, extravasation, inflammation, suppuration, and every ill which can attend on or be found in the latter, are to be met with in the former, and will require the same method of treatment." That loose splintered pieces of the cranium, when quite detached, and already in view, in consequence of the scalp being wounded, ought to be taken away, no one will be inclined to question. That they ought also to be exposed by an incision, even when the scalp is unwounded, and then taken away whenever they cause symptoms of irritation or pressure, I believe will be universally allowed. But the reader will already understand, from what has been said in the preceding section, that several excellent surgeons do not coincide with Pott in believing that every depressed fracture of the skull necessarily demands the application of the trephine.

"There certainly are (says Mr. Abernethy) degrees of this injury, which it would be highly imprudent to treat in this manner. Whenever the patient retains his senses perfectly, I should think it improper to trephine

him, unless symptoms arose that indicated the necessity of it."—(*P* 21.)

It is extraordinary and unaccountable, but it is not less true, that no calculation of the bad effects can be made by the degree in which a part of the skull is depressed This is a fact which has been long known. It has also been particularly adverted to by an eminent modern writer. "Various instances also presented themselves, in which, though a considerable degree of compression must have been occasioned, sometimes by the depression of both tables, and at other times by the depression of the inner table only of the skull, yet neither stupor, paralysis, nor loss of memory was produced. In one of these cases the middle of the right parietal bone was fractured, and considerably depressed by a ball, which was extracted on the 20th day. In this case, neither stupor nor paralysis appeared. In another, a musket-ball had struck the right parietal bone, fractured it, and was flattened and lodged between the tables of the skull. The inner table was much depressed, yet no bad symptoms supervened."—(See *Thomson's Observations made in the Military Hospitals in Belgium, p.* 59, 60.) The same author also saw a singular case, in which a ball, entering behind the right temple, and passing backwards and downwards, had fractured the bones in its passage, and lodged in the surface of the brain, over the tentorium, from which place it was extracted on the seventeenth day after the injury. No bad symptom had manifested itself previously to the operation, and the man recovered, under the strictest antiphlogistic regimen, with little or no constitutional derangement. Dr. Hennen has recorded two cases, fully proving the correctness of Mr. Abernethy's opinions about the impropriety of using the trephine in cases of depression unattended with urgent symptoms: in one of these instances, the upper and posterior angle of the parietal, which had been struck by a musket-ball, was depressed exactly *an inch and a quarter from the surface of the scalp, yet no bad symptoms followed*, and with the aid of bleeding and other antiphlogistic remedies, the soldier recovered perfectly in a few weeks. "In a similar case, where the man survived thirteen years, with no other inconvenience than occasional determination of blood to the head on hard drinking, *a funnel-like depression to the depth of an inch and a half* was formed in the vertex."—(See *Hennen's Military Surgery, p.* 287, *ed.* 2.)

If then the violence of the symptoms is not always in proportion to the compression, but is sometimes considerable when the pressure is slight, every surgeon cannot be too fully impressed with the following truth, that *existing symptoms of dangerous pressure on the brain*, which symptoms will be presently related, *can alone form a true reason for perforating the cranium.*

Although the doctrines of Sir Astley Cooper, generally speaking, coincide very much with the preceding maxim, which I regard as a very important one; there is an exception to it in his advice, in relation to compound fractures of the skull, as will be understood from the following passage. "The old practice used to be, the moment an injury of the brain was suspected, and the least depression of the bone appeared, to make an incision into the scalp. This is putting the patient to considerable hazard; for the simple fracture would by the incision be rendered compound. In simple fracture, then, when it is attended with symptoms of injury of the brain, deplete before you trephine; and when it is unattended with such symptoms, deplete merely, and do not divide the scalp, &c. If the fracture be compound, the treatment must be very different; because a compound fracture is very generally followed by inflammation of the brain; and it will be of little use to trephine, when inflammation is once produced. If the inflammation come on, the patient will generally die, whether you trephine or not," and it is added, that the operation will even be likely to increase the inflammation, which has been excited by a depressed portion of the skull. "The rule (says Sir Astley) which I always follow, is this: when I am called to a compound fracture with depression, which is exposed to view, whether symptoms of injured brain exist or not, I generally use an elevator, and very rarely the trephine. I put the elevator under the bone, raise it, and if it has been comminuted, remove the small portions of bone."—(*Lectures, &c. vol.* 1, *p.* 304. 308.) Of the propriety of using the elevator in such cases, and also of taking away loose fragments, there cannot be a doubt; but many surgeons object (and I confess myself one of the number) to saw out a portion of the skull while the patient is free from urgent symptoms. I believe, also, that the inflammation, when it does arise, is mostly the effect of the violence itself, not of the depression of the bone, and, therefore, more likely to be increased than prevented by the application of the trephine. I think a better reason for elevating the bone, when it is exposed, and there are no bad symptoms, is the fact that many patients, after their recovery from the imminent danger of the accident, become subject, whenever the circulation is hurried, to insanity, epilepsy, &c. Yet, here it is to be considered, that it may be quite time enough to trephine, when such ills follow the continuance of the depression, and that, perhaps, the operation would then be in itself less dangerous, inasmuch as the tendency to inflammation, arising from the first violence, must now have subsided.

In children a portion of the skull is sometimes depressed or indented by a blow, but in a few days regains its natural level without the aid of the surgeon. In such examples, it is conceived by Mr. Brodie, that the earthy part of the bone gives way, while the animal part remains entire, so that there is not an actual solution of continuity, and he supposes that the restoration of the bone to its proper level is brought about by the constant pulsations of the brain against its inner surface.—(See *Med. Chir. Trans. vol.* 14, *p.* 332.)

Sometimes a considerable depression of the bone arises from the external table being driven into the diploe, while the inner table is entire. To trephine, therefore, merely because there is a depression of the bone, would be completely erroneous, and the only safe principle is that which I have just now specified. The depression of the outer table in the foregoing manner I have never seen myself; Sir Astley Cooper, however, mentions it as a frequent occurrence; but that it is confined to persons of middle age, as in very young and very old persons the skull is thin and without diploe.—(*Lectures, vol.* 1, *p.* 302.) Another sort of depression, I believe, is more frequent; at least, I have seen several examples of the case; it consists in a fracture and depression of the internal table, while the external one continues unbroken. A case of this kind, attended with urgent symptoms of compression, I trephined at Brussels; a large splinter of the inner table was driven more than an inch into the brain, and on its extraction the patient's senses and power of voluntary motion instantly returned. Part of the skull to which the trephine was applied, of course, did not indicate externally any depression, and it was selected because the appearance of the scalp showed, that there the external violence had operated. I rather expected to find extravasated blood, than a depression of the inner table of the skull.—(See also *Saucerotte, in Mém. pour le Prix de l'Acad. de Chir. t.* 4, *éd.* 1819, *p.* 322. *Hennen's Military Surgery, p.* 323, *ed.* 2; *and B. C. Brodie, in Med. Chir. Trans. vol.* 14, *p.* 331.)

In military surgery particular cases present themselves, which scarcely admit of being comprehended within the tenor of any general rules and principles. Thus, it sometimes happens, that a ball breaks the os frontis, and the whole or a part of it lodges in the frontal sinus, with or without fracture of the inner boundary of this cavity. In cases of this description, Baron Larrey recommends exposing the course of the fracture by a free incision, and the use of the trephine for the removal of the extraneous body. When the inner side of the sinus was found broken and depressed, he next perforated that part of the cavity with a small conical trephine, took away such pieces of bone as required removal, and let out any extravasated blood Sometimes, however, the front of the sinus is so splintered, that the fragments, when taken away with the forceps, leave the cavity sufficiently opened, not only for the extraction of the ball, but for the application of the trephine to the inside of the sinus as we find exemplified in one of the two cases of this nature which Larrey met with in the Egyptian campaign.—(*Mém de Chir. Militaire, t.* 2, *p.* 138.) After the battle of Witepsk, in 1812, he was called to two Russian soldiers, whose cases were remarkable; one of them had been struck above the right eyebrow with a grape-shot, which, after breaking and penetrating the frontal bone, entered the cavity of the cranium, so as to lodge upon the anterior right lobe of the brain, and the orbitar process and internal crista of the os frontis. Notwith-

standing the large size of the ball, little of it could be seen externally, and the aperture through which it had passed was not more than three or four lines broad; every attempt to extract it, therefore, was in vain. The patient experienced a painful sense of oppression and weight in the head, and, whenever he inclined it backwards, was seized with syncope. He kept himself constantly in a sitting posture with his head on his knees. Larrey adds, that every symptom of compression of the brain also prevailed, though this account is rather difficult to comprehend, considering that the patient could sit up, and choose his posture. As for any description given by himself of his sufferings, that is another circumstance on which I should not be inclined to dwell, because in all probability the baron was not able to converse in the Russian language, and the inferences respecting the man's feelings were made in some other way. But whatever might be the real state of the symptoms (and in a case of this kind a correct account of them would have been interesting), the ball was plainly ascertained, by means of a probe, to be of iron, and of much larger diameter than the opening through which it had entered; and that for the purpose of extracting it the application of the trepan was urgently necessary. The fracture was fairly brought into view by suitable incisions; three perforations were made with a small trephine at its upper part, and after the removal of the angles of the bone between these perforations, the ball, which weighed seven French ounces, was readily extracted with the aid of a strong pair of forceps and an elevator. A considerable quantity of coagulated blood was also removed, under which the brain was found with a depression of three or four lines deep. As soon as some splinters of the bone had been taken away, the part was dressed with a bit of fine linen dipped in warm wine, sweetened with sugar, over which were placed charpie, several compresses, and a bandage. With respect to the application of warm wine and other stimulants to the surface of the brain, in wounds exposing or interesting that organ, it seems to be an invariable practice with Larrey, as well as Schmucker, and the older surgeons. On what principle the custom is still kept up, and whether it is truly right and useful, are questions which may be rationally put. In whatever way experience may hereafter decide these matters, suffice it to add, that the patient was relieved by the treatment, and fell into a quiet sleep for two hours; but in the evening he became feverish, and the wound acutely painful. A considerable quantity of blood was taken from the vena saphena (and why bleeding was not practised at first, seems extraordinary). The dressings, which, according to my ideas, were highly objectionable, were removed, and a large emollient poultice applied. Cooling beverages, containing a small quantity of tartarized antimony, and antispasmodic anodyne medicines were prescribed. The following day the patient's state appeared satisfactory, without the slightest disturbance of the senses, and in one time he perfectly recovered.

The other soldier had been wounded in the left temple with a leaden ball, five days before Larrey saw him. One half of the ball had gone into the cranium, through a very narrow breach; the other had burrowed under the temporal muscle, and lodged near the mastoid process. The right side of the body was paralytic, the senses were annihilated, and the man was in a state of incessant agitation. After dilating the wound in the temple, and exposing the fracture, Larrey discovered the track of the piece of lead, which had gone towards the mastoid process, and which he immediately extracted by a counter-opening. At the lower part of the temporal wound, he applied a trepan very near the spot where the other portion of the ball was lodged. This, with some fragments of the bone, and a quantity of extravasated blood, was easily extracted. The patient, however, was not saved; a circumstance ascribed by Larrey to the operation having been done too late.

In another case, one of the imperial guards, wounded at the battle of the Moskowa, died with symptoms of compression, and, after death, a quarter of a bullet, and a fragment of bone were found under the skull, attended with an ulcerated or wounded state of the adjacent portion of the brain. Larrey very properly expresses his opinion, that this soldier would have had a chance of being saved, had the trepan been used — (See *Mém. de Chir. Mil. t.* 4, *p.* 183, *&c.*) The practice of trephining for the removal of balls, situated near a fracture of the skull, within this bony cavity, or lodged among the fragments, or between the two tables forced asunder (see *Engel's case, in Vermischte Chir. Schriften von J. L. Schmucker, b.* 1, *p.* 242), is not peculiar to Larrey, for it has been done by many other surgeons (see *Schmucker's Wahrnehmungen, b.* 1, *p.* 298); but I do not know that he has been anticipated in his bold practice of making a counter-opening in the skull, when the ball is lodged at such a distance from the fracture, that it cannot be extracted through any perforation made in the vicinity of the original injury; for it is a principle which he ventures to lay down, that *when a ball has entered the cranium, without quitting the roof of this cavity, the case is one requiring the application of the trepan.*—(*Mém. de Chir. Mil. t.* 4, *p.* 180.) In the 2d vol. of this work (*p.* 139), the reader will find the account of a soldier, who was struck on the middle of the forehead with a ball which penetrated the os frontis, and then passed obliquely backwards, between the skull and the dura mater, in the course of the longitudinal sinus, as far as the lambdoidal suture, where it stopped. Larrey traced the situation of the ball, by the introduction of an elastic gum catheter into the opening; and measuring the distance between the fracture and the place where he felt the ball, he cut down upon that part of the skull, beneath which he concluded that the ball was lodged. The bone was then perforated with a large trepan; *a good deal of pus was discharged;* the ball was extracted, and the patient recovered. One thing here merits the attention of surgeons: Larrey tells us, that a good deal of pus issued as soon as an opening was made in the skull: there must then have been suppuration under the bone, and inflammation and detachment of the dura mater; circumstances always indicated, according to Pott, by a corresponding separation of the pericranium, and a puffy tumour of the scalp. Did these symptoms take place in the foregoing case, so as to be of any assistance to Larrey, in judging of the place where the ball was lodged? and has the mention of them been omitted only by accident? or are we to infer that suppuration may happen between the cranium and dura mater, without any detachment of the pericranium and puffy tumour of the scalp? a thing which Bichat asserts is proved by daily experience in the Hôtel-Dieu, at Paris.—(See *Œuvres Chir. de Desault, t.* 2, *p.* 29.) Larrey, in his 3d vol. (*p.* 82), gives us another case, in which a ball pierced the left parietal bone, and lodged near the lambdoidal suture. Its situation was detected with the aid of an elastic gum catheter, and partly in consequence of there being a slight ecchymosis over the part. Here a crucial incision was made through the scalp, and a small fissure discovered. As the symptoms of compression increased, the trepan was applied, so as to include the fissure. A half of the ball flattened was found directly under the perforation, and a good deal of blood was voided from the two openings in the cranium. For a fortnight the case went on favourably, but the patient was then attacked with what Larrey terms hospital fever, but which in all probability was inflammation and suppuration of the membranes of the brain, and died.

The records of surgery furnish numerous instances in which the patients lived a considerable time with balls lodged in the cavity of the cranium. Thus, one is related by Paroisse, where the patient soon recovered his senses after the injury, and at the end of six months felt no inconvenience, except a difficulty of opening the mouth.—(*Opuscules de Chir. Obs.* 1, 8*vo. Paris*, 1806.) Ramdohr has published another case, where a soldier was shot through the frontal sinus, and the ball was found after death in the medullary substance of the left hemisphere of the brain, half an inch above the ventricle; yet this patient lived four months after the injury, and soon recovered his senses after its occurrence. For a considerable part of this time he was also free from any bad symptoms. At last he was affected with a kind of stupor, and an inability to open his left eye, and fell into a lethargic and convulsed state.—(*Schmucker, Vermischte Chir. Schriften, b.* 1, *p.* 277.) A French soldier, at the battle of Waterloo, was wounded with a musket-ball, which entered at the anterior portion of the squamous suture, lodged in the substance of the brain, and on the fifth day after an enlargement of the wound, and the removal of seve-

ral fragments of bone, was extracted from the posterior lobe of the right hemisphere of the brain, where it was found resting on the tentorium. Yet, during the several previous days, the man, with the exception of a slight headache, and partial deafness of the right ear, seemed to enjoy perfect health. The case ended well. —(See *Hennen's Mil. Surg. p.* 289, *ed.* 2.) Still more remarkable instances of the duration of life, and even of the absence of very serious symptoms, after great and serious wounds of the brain, and the lodgement of balls, might here be cited; but it will suffice to refer to the instructive Essay of M. Quesnay on the subject, in vol. 1, of the *Mém. de l'Acad. de Chir.* 4to., and to the account of twenty-two French soldiers, whose vertices, with more or less of the brain, were cut off by sabre-strokes. All these men ultimately died; but at first had not a single bad symptom, and performed a journey of thirty leagues after being wounded, and one-half of this distance on foot.—(See *Paroisse, Opuscules de Chir. p.* 41, *&c.*)

5. Extravasation under the Cranium, Symptoms of Pressure on the Brain, &c.

Mr. Pott remarks, "the shock which the head sometimes receives by falls from on high, or by strokes from ponderous bodies, does not unfrequently cause a breach in some of the vessels either of the brain or its meninges, and thereby occasions extravasation of the fluid which should circulate through them. This extravasation may be the only complaint produced by the accident; or it may be joined with, or added to, a fracture of the skull. But this is not all; for it may be produced not only when the cranium is unhurt by the blow, but even when no violence of any kind has been offered to or received by the head."

The effused blood may lie between the cranium and dura mater; between the latter membrane and the arachnoides; on the surface of the pia mater, or under this membrane, on the surface, in the substance, or cavities of the brain. The first species of extravasation, which is observed to be always more or less circumscribed, may occur at any part of the skull, but when situated at its base, is generally fatal. In the second, which is the most common species of extravasation within the dura mater (see *Brodie, in Med. Chir. Trans. vol.* 14, *p.* 333), the blood is widely scattered about between the dura mater and arachnoides, and on this account, unless its quantity be very considerable, it does not cause any great degree of pressure. In the third example, if the blood be situated in the convolutions, it is also widely diffused, but if it be within the substance or ventricles of the brain, which is rare (*Brodie, vol. cit.*), it is circumscribed.—(*Œuvres Chir. de Desault, t.* 2, *p.* 23.) Sometimes in cases of great violence, as Mr. Pott has justly observed, the blood is found at the same time in all these different parts.

According to Mr. Brodie's experience, which confirms the observations of Mr. Abernethy, there is never such hemorrhage from a rupture of the blood-vessels, by which the dura mater is connected to the bone, as will produce dangerous pressure on the brain, except when the middle meningeal artery has been lacerated, from which vessel the bleeding is sometimes very copious. Mr. Brodie has never seen this artery lacerated, except in the combination with a fracture running across the bony canal in which it is situated; but he adverts to other cases, recorded by Mr. Latta and Mr. Abernethy, in which no such fracture accompanied the rupture of the vessel.—(See *Med. Chir. Trans. vol.* 14, *p.* 333.)

Another observation made by Mr. Brodie is, that large extravasations are sometimes found upon the upper surface of the brain, but more frequently at its basis, where they are usually the consequence of a rupture of the substance of the brain. The same surgeon has never seen an instance, in which the blood from a wounded sinus collected between the dura mater and the skull, or between that membrane and the brain, in sufficient quantity to interfere with the functions of the latter organ.

When the blood is extravasated beneath the skull, the violence which produces the rupture of the vessel usually stuns the patient, from which state, provided the quantity and pressure of the blood and the force of the concussion be not too great, he gradually recovers and regains his senses. If the first extravasation be trivial, the patient, after regaining his senses, may only feel a little drowsiness and go to bed. The bleeding from the ruptured vessel continuing, and the pressure on the brain increasing, he becomes more and more insensible, and begins to breathe in a slow, interrupted, stertorous manner. In cases of compression, whether from blood or a depressed portion of the skull, there is a general insensibility; the eyes are half open; the pupils dilated and motionless, even before the vivid light of a candle; the retina is insensible; the limbs relaxed; the breathing stertorous; the pulse slow, and, according to Mr. Abernethy, less subject to intermission, than in cases of concussion. The absence of stertor, however, as this gentleman admits, must not be relied upon as a proof of their being no compression; for Morgagni relates dissections of apoplectic persons, in whom the effusion was considerable, yet no stertor had occurred.

In a case of wound of the posterior part of the skull, with depression, seen by Dr. J. Thomson, the pulse at one time sunk as low as 36 strokes in a minute. This eminent professor, however, is at variance with Mr. Abernethy upon one point, by stating that irregularity of the pulse is a frequent attendant upon compressed brain.—(*Report of Obs. &c. p.* 54, 55.)

Mr. Brodie does not give any positive opinion on the statement made by Mr. Abernethy, that intermission of the pulse is less frequent in compression than concussion; but he expresses his belief, that pressure on the brain for the most part affects the action of the heart; *not by producing actual interruption, but by causing its contractions to be either less frequent, or less forcible than natural.*—(*Med. Chir. Trans. vol.* 14, *p.* 355.) In the cases referred to in Dr. Thomson's report, convulsions sometimes arose from the pressure of portions of the skull, forced inwards upon the brain. This is a very dangerous symptom; but Dr. Thomson saw it cease in a few examples, after the depressed piece of bone had been elevated, and the antiphlogistic regimen adopted.—(*P.* 60.) Convulsions I am disposed to regard, with Bichat, rather as a symptom of injury of the brain, than of compression.—(*Œuvres Chir. de Desault, t.* 2, *p.* 27.)

Mr. Brodie, seemingly unaware of the corresponding remark published in the foregoing work, considers it questionable, whether convulsive twitches of the muscles ought to be regarded as the consequence of simple pressure on the brain? We find them occur, says he, in cases of punctured and wounded brain, where there is no pressure; and whenever he has noticed them as attendant on depression of the skull or extravasated blood, and has afterward had the opportunity of ascertaining the exact nature of the injury, the *pressure has always been found to be complicated with wound or laceration of the substance of the brain.* The convulsive twitches to which Mr. Brodie alludes, he particularly describes as slight and partial, and different from the more violent and general convulsions. —(See *Med. Chir. Trans. vol.* 14, *p.* 352.)

Indeed, the difficulty of the diagnosis of many cases may be well conceived by what Dr. Hennen remarked in his practice; viz. that in some instances the pupils were contracted, in others dilated, where the injury was nearly of a similar nature and degree; while sometimes, in the same patient, one pupil was dilated and the other much contracted. He saw, also, paralysis occur on one side, and convulsions on the other, when the blow had been on the forehead, and the same when it had been on the occiput.—(*Op. cit. p.* 300, 301.)

Mr. Brodie has seen the pupils dilate with the absence, and contract with the presence of light, although the patient lay in a state of complete insensibility, and did not seem to be at all conscious of the impressions made on the retina. He admits, however, that this is a rare occurrence, and that, when the other symptoms of pressure are present, the *pupils are generally insensible and motionless, and mostly dilated*, though sometimes contracted. Every surgeon of experience must be aware of another circumstance mentioned by the same surgeon; namely, that it is not uncommon for the pupils to remain for a time in a state of dilatation, then to become suddenly contracted, and after remaining so for a longer or shorter time, to become again dilated; these changes taking place independently of light and darkness. When the pupils have been dilated, Mr. Brodie has frequently known them to become contracted after the abstraction of blood; the dilatation

returning as soon as the immediate effect of the bloodletting had ceased. He adverts to a curious case, reported by Dr. Hennen, in which blood was extravasated between the membranes of the brain, and the pupils sometimes dilated in an increased light, and contracted in a diminution of it.—(See *Med. Chir. Trans. vol.* 14, *p.* 352.) Another observation made by Mr. Brodie is, an occasional insensibility of one iris, dilatation of the pupil, and aptosis, continuing after the subsidence of the general insensibility of the body, and even unattended with loss of vision.—(*Vol. cit. p.* 354.)

The patient is hardly ever sick when the pressure on the brain and the general insensibility are considerable; for the very action of vomiting betrays sensibility in the stomach and œsophagus. The truth of this statement, which agrees with Mr. Abernethy's experience, is strikingly confirmed by an observation made by Mr. Brodie; namely, that when he has had occasion to apply the trephine on account of a fracture and depression, and no sickness existed previously, he has sometimes known the patient become sick and vomit immediately the depressed bone was elevated.—(See *Med. Chir. Trans. vol.* 14, p. 356.) These symptoms are not peculiar to pressure from blood, but arise also from that of many depressed fractures of the skull and of suppuration under this part. They are all attributable to the unnatural pressure made on the brain and nerves, and have too often been mistaken as indications of an injury, which, considered abstractedly, can never cause them; I allude to a simple undepressed fracture of the cranium, which may be accompanied with them but cannot cause them. They differ in degree according to the quantity, kind, and situation of the pressing fluid. The hemorrhage from the nose and ears, which often follows violence applied to the head, is generally conceived to lead to no particular or useful inference: we cannot even calculate, by this sign, that the force has exceeded a certain degree; for such bleedings take place from much slighter causes in some persons than others.

Mr. Brodie's observations on this point merit attention: "There is often a considerable effusion of blood from the ear, especially in cases of fracture of the basis of the cranium. This may, as far as I know, sometimes arise from other sources; but it seems probable that it must in most instances arise from the laceration of the lateral sinus, where it extends downwards behind the petrous process of the temporal bone and the external meatus; and in one instance I ascertained it to have been so by the examination of the body after death. In another case which fell under my observation, there was hemorrhage both from the ear and the nostrils. The patient, a boy, died shortly after the accident; and it was found, on dissection, that there was a fracture of the base of the cranium, with laceration of the cavernous sinus, and that the hemorrhage had taken place from this sinus."—(See *Med. Chir. Trans. vol.* 14, *p.* 334.) According to my experience, bleedings from the ear and nose from injuries of the head are particularly frequent in children, and often manifestly consist of arterial blood.

Paralysis is a symptom which generally attends hurtful pressure on the brain. The particular circumstances, however, which determine its degree, extent, and situation, are not well understood. "In some instances of paralysis from sabre-wounds, as well as in those made by gun-shot (says Dr. J. Thomson), paralysis was confined to the upper, and in others to the lower extremity. *In every instance in which it distinctly appeared that the injury existed on one side of the head, the paralysis uniformly manifested itself upon the other;* but we were unable to perceive any other fixed relation between the part of the brain which had been injured and the part of the body affected with palsy. A wound of the right parietal bone by a musket-ball was followed by palsy of the left arm and leg. In another case, a wound penetrating the upper part of the right parietal bone was accompanied with a slight paralytic affection of the left side of the mouth, and complete palsy of the left leg. In a third case, a sabre-wound of the same bone, followed by extensive exfoliations, gave rise to a complete palsy of the left side."—(*Obs. made in the Military Hospitals in Belgium, p.* 52, 53.)

When the destruction of sensibility is complete, the voluntary muscles are entirely paralyzed. The patient lies motionless in any position in which he happens to be placed. The bladder, incapable of contraction, becomes preternaturally distended with urine; and the relaxation of the sphincter ani allows the involuntary discharge of feces from the rectum. Afterward the muscles of respiration become affected also; the patient breathes with stertor, as in a most profound sleep; and the diaphragm contracts at longer and longer intervals, until respiration altogether ceases. It is this paralysis of the muscles of respiration which in ordinary cases of pressure on the brain is the immediate cause of death. When the loss of sense is imperfect, there are often no marks of paralysis whatever. At other times, there is hemiplegia, which, however, is much more rarely the consequence of accidental violence than of apoplexy. Mr. Brodie conceives that this difference is referrible to the different situation of the pressure. In apoplexy, the extravasation is mostly situated in one of the ventricles, or in the substance of the brain; but after a blow on the head, the cause of pressure commonly operates upon the surface.—(*Med. Chir. Trans. vol.* 14, *p.* 349, 350.)

With respect to paralysis, it is unquestionably one of the common symptoms of pressure on the brain; but, according to Bichat, it may also be caused by concussion; and we know that it may arise in cases of inflammation and suppuration within the skull. The above statement respecting the paralysis being always on the side of the body opposite that on which the brain is compressed, agrees with what is generally remarked by other surgical writers.—(See *Larrey's Mém. de Chir. Mil. t.* 4, *p.* 180; *Hennen's Principles*, p. 301, *ed.* 2, *&c.*) Yet, at the Hôtel-Dieu, at Paris, extravasation has very often been noticed both on the side affected with paralysis and on the opposite one; or else the blood was generally diffused, while the paralysis was local.—(*Œuvres Chir. de Desault, t.* 2, *p.* 27.)

The preceding class of symptoms only informs us, that the brain is suffering compression; and leaves us quite in the dark respecting several other very important circumstances. "We not only have no *certain infallible* rule, whereby to distinguish what the pressing fluid is, or where it is situated, but we are, in many instances, absolutely incapable of knowing whether the symptoms be occasioned by any fluid at all; *for a fragment of bone broken off from the internal table of the cranium, and making an equal degree of pressure, will produce exactly the same complaints.*"—(*Pott.*) In detailing the symptoms of pressure from blood, I took particular notice of the patient being at first generally stunned by the blow, of his gradually regaining his senses, and of his afterward relapsing into a state of insensibility again. *The interval of sense* which thus occurs, was pointed out by Petit as a circumstance of the greatest consequence in elucidation of the nature of the case.

"A concussion and an extravasation (as Mr. Pott observes) are very distinct causes of mischief, though not always very distinguishable.

M. Le Dran, and others of the modern French writers, have made a very sensible and just distinction between that kind and degree of loss of sense which arises from a mere commotion of the brain, and that which is caused by a mere extravasation, in those instances in which the time of the attack or appearance of such symptoms are different or distinct. The loss of sense which immediately follows the violence, say they, is most probably owing to a commotion; but that which comes on after an interval of time has passed is most probably caused by extravasation.

This distinction is certainly just and good as far as it will go. That degree of abolition or diminution of sense which immediately attends or follows the blow or fall, and goes off again without the assistance of art, is in all probability occasioned by the sudden shake or temporary derangement of the contents of the head: and the same kind of symptoms recurring again some time after they had ceased, or not coming on until some time has passed from the receipt of the violence, do most probably proceed from the breach of a vessel within or upon the brain. But, unluckily, we have it not very often in our power to make this exact distinction. An extravasation is often made so immediately, and so largely, at the instant of the accident, that all sense and motion are instantaneously lost, and never again return. And it also sometimes happens, that although an extravasation may possibly not have been made at the moment of the accident, and the first complaints may have been owing to commotion merely, yet

a quantity of fluid having been shed from its proper vessels very soon after the accident, and producing its proper symptoms, before those caused by the commotion have had time to go off, the similarity of the effects of each of these different causes is such, as to deprive us of all power of distinguishing between the one and the other, or of determining, with any tolerable precision, to which of them such symptoms as remain are really owing."

A man meets with a fall; a slight concussion of the brain is the consequence, and the patient is instantly stunned. The effects of concussion gradually subside, but an extravasation takes place, and the loss of the senses continues, though from a different cause. Here, according to the principles of Petit, the case would be set down as concussion; yet, things are quite the contrary, the extravasation now keeping up the symptom which was only temporarily produced by concussion. In many instances, also, the effects of concussion and extravasation exist together, and then how is a surgeon to judge of the nature of the case?—(See *Œuvres Chir. de Desault, t.* 2, *p.* 25.)

"When an extravasation of any kind is made either upon or within the brain, if it be in such quantity, or so situated, as to disorder the economy of the animal, it always produces such disorder by making an unnatural pressure on the parts where it lies. The nature and degree of the symptoms hereby produced are various and different in different persons, according to the kind, quantity, and situation of the pressing fluid. Sometimes it is merely fluid blood, sometimes blood in a state of coagulation; sometimes it is a clear lymph, and at others blood and water are found mixed together: each of these is found either simple or mixed in different situations, that is, between the skull and dura mater, between the dura and pia mater, or in the natural cavities of the brain called its ventricles, and sometimes, in cases of great violence, they are found at the same time in all these different parts. Sometimes a considerable quantity is shed instantly at the time of the accident; and sometimes the breach by which the effusion is made is so circumstanced, both as to nature and situation, that it is at first very small, and increases by faster or slower degrees. In the former, the symptoms are generally immediate and urgent, and the extravasation is of the bloody kind; in the latter, they are frequently slight at first, appear after some little interval of time, increase gradually till they become urgent or fatal, and are in such case generally occasioned by extravasated lymph. So that although the immediate appearance of bad symptoms does most certainly imply mischief of some kind or other, yet, on the other hand, no man ought to suppose his patient free from hazard, either because such symptoms do not show themselves at first, or because they appear to be but slight; those which come on late, or, appearing slight at first, increase gradually, being full as much to be dreaded, as to consequence, as the more immediately alarming ones; with this material difference between them, that the one *may* be the consequence of a mere concussion of the brain, and may by means of quietude and evacuation go quite off; whereas, the other being most frequently owing to an extravasation of lymph (though sometimes of blood also) within the substance of the brain, are very seldom removed by art."—(*Pott.*)

The case of extravasation between the cranium and dura mater is almost the only one which admits of relief from trephining. Mr. Abernethy informs us, that in the cases which he has seen of blood extravasated between the dura and pia mater, on a division of the former membrane being made for its discharge, only the serous part of it could be evacuated; for the coagulum was spread over the hemisphere of the brain, and had descended as low as possible towards its inferior part, so that very little relief was obtained by the operation.—(*Surgical Works, vol.* 2, *p.* 46.) This statement is confirmed by that of Bichat, and the practice inculcated agrees with what Sir Astley Cooper also directs, as will be presently noticed.

Fractures of the cranium which take place across the lower and front angle of the parietal bone, and the rest of the track of the trunk, and large branches of the spinous artery of the dura mater, are cases very apt to be attended with a copious extravasation. This vessel, and others more deeply seated, however, may be ruptured, pour out a considerable quantity of blood, and induce urgent symptoms of pressure on the brain, not only without the co-existence of a fracture, but even of any external mark of violence on the scalp.

The effused blood is frequently situated below the part on which the violence has operated, and hence, when such part is pointed out by a wound or discoloration of the scalp, or a fracture, and the symptoms of pressure are considerable, I should have no hesitation about immediately trephining in the situation of the external injury. I have seen many cases in which such practice was justified by the result, and even when no extravasation exists, this plan will sometimes detect a depression of the inner table of the skull, and be the means of saving life, as happened in one very remarkable case, which I trephined at Brussels after the battle of Waterloo. At the same time, it would be wrong to hold out the expectation, that by acting on this principle, the surgeon will always find blood immediately under the part of the cranium which he perforates. With respect to a fracture also, as a guide to the place for the application of the trephine in cases of extravasation, Desault regards it as very fallacious, dissections proving that numerous fractures of the skull are unattended with any effusion of blood immediately under them; and his experience taught him that the most frequent cases were those in which there was either extravasation without fracture, or a fracture with blood effused in a part of the head remote from the injury of the bone.—(*Œuvres Chir. t.* 2, *p.* 130.) Even when blood is seen issuing from the fissure, he regards it as no proof of the dura mater being detached, as such blood may proceed from the vessels of the diploe.—(*P.* 31.) But what is to be done when dangerous symptoms of pressure prevail, without any external mark to denote what part of the head has received the blow, or whether any at all? for a general concussion of the head may produce an effusion of blood within the cranium. Under these circumstances, Mr. Pott was against the operation, and says, that "the only chance of relief is from phlebotomy and an open belly; by which we may hope so to lessen the quantity of the circulating fluids as to assist nature in the dissipation or absorption of what has been extravasated. This is an effect which, although not highly improbable in itself, yet is not to be expected from a slight or trifling application of the means proposed. The use of them must be proportioned to the hazard of the case. Blood must be drawn off freely and repeatedly, and from different veins; the belly must be kept constantly open, the body quiet, and the strictest regularity of general regimen must be rigidly observed. By these means, very alarming symptoms have now and then been removed, and people in seemingly very hazardous circumstances have been recovered." Desault also promulgated the same advice, and blamed the doctrine formerly in vogue, that it was better to apply the trephine many times uselessly than to let a single extravasation remain undetected; for he was firmly convinced that the trephine, when used on this principle, was a source of greater mischief than the effused blood itself.—(*Œuvres Chir. t.* 2, *p.* 34.) The same doctrine is espoused by Sir Astley Cooper (*Lectures, &c. vol.* 1, *p.* 288), and, I believe, by all the best modern surgeons.

But should the mode of judging whether blood lies immediately under the skull, suggested by Mr. Abernethy, prove invariably correct, the question whether the trephine should be applied or not, may in future be more easily determined. Even when the injured scalp shows where the violence has operated, the criterion about to be noticed may inform us whether we should perforate the bone or not; for though the extravasation is sometimes found immediately under the external mark, yet it often is not so, but is in a part distant from that mark, to which situation we have nothing to lead us, and to which, indeed, if we knew it, we could not reach. Mr. Abernethy has observed, "that unless one of the large arteries of the dura mater be wounded, the quantity of blood poured out will probably be inconsiderable; and the slight compression of the brain, which this occasions, may not be attended with any peculiar symptoms, or perhaps it may occasion some stupor, or excite an irritation, disposing the subjacent parts to become inflamed. It is indeed highly probable, that in many cases which have done well without an operation, such an extravasation has existed. But if there be so much blood on the dura mater as materially to derange the functions of the brain, the bone, to a

certain extent, will no longer receive blood from within, and by the operation performed for its exposure, the pericranium must have been separated from its outside. I believe that a *bone so circumstanced will not be found to bleed;* and I am at least certain it cannot with the same freedom and celerity as it does when the dura mater remains connected with it internally."—(See *Abernethy's Surgical Works, vol.* 2, *p.* 47.) In some cases related by this gentleman, there was no hemorrhage; twice he was able, by attending to this circumstance, to tell how far the detachment of the dura mater extended; and often, when symptoms seemed to demand a perforation of the skull, he has seen the operation contra-indicated by the hemorrhage from the bone, and, as the event showed, with accuracy. Mr. Abernethy admits, however, that in aged persons, and in those in whom the circulation has been rendered languid by the accident, the mode of distinction which he has pointed out will be less conclusive.

Pott remarks, that "if the extravasation be of blood, and that blood be in a fluid state, small in quantity, and lying between the skull and dura mater, immediately under or near to the place perforated, it may happily be all discharged by such perforation, and the patient's life may thereby be saved; of which many instances are producible. But if the event does not prove so fortunate, if the extravasation be so large or so situated that the operation proves insufficient, yet the symptoms having been urgent, general evacuation having been used ineffectually, and a wound or bruise of the scalp having pointed out the part which most probably received the blow, although the removal of that part of the scalp (a simple incision ought to have been said) should not detect any injury done to the bone, yet the symptoms still subsisting, I cannot help thinking that perforation of the cranium is in these circumstances so fully warranted, that the omission of it may truly be called a neglect of having done that which might have proved serviceable, and, *rebus sic stantibus*, can do no harm. It is very true, that no man can beforehand tell whether such operation will prove beneficial or not, because he cannot know the precise nature, degree, or situation of the mischief; but this uncertainty, properly considered, is so far from being a dissuasive from the attempt, that it is really a strong incitement to make it; it being fully as impossible to know that the extravasated fluid does *not* lie between the skull and dura mater, and that under the part stricken, as that it *does;* and if the latter should be the case, and the operation be not performed, one, and most probably the only, means of relief will have been omitted."

On some of the foregoing points, Mr. Brodie's advice coincides very much with the precepts of Mr. Abernethy, and with the doctrines which have been for many years inculcated in this work. Blood, he observes, is seldom poured out in any considerable quantity between the dura mater and the bone, except in consequence of a laceration of the middle meningeal artery, or one of its principal branches. If, therefore, we find the patient lying in a state of stupor, and discover a fracture with or without depression, extending in the direction of the middle meningeal artery, Mr. Brodie is an advocate for the trephine. When no fracture is discoverable, but there is other evidence of the injury having fallen on that part of the cranium under which the middle meningeal artery is situated, the trephine, he says, may be employed on speculation, rather than that the patient should be left to die without any attempt being made for his preservation.—(See *Med. Chir. Trans. vol.* 14, *p.* 385.)

When there is no interval of sense between the blow and the coming on of perilous symptoms, it is frequently impossible to determine whether the mischief be owing to the largeness and suddenness of the extravasation, to the violence of the shock which the brain has received, or to both these causes at once, which, unfortunately, is too often the case. In this latter complication, indeed, trephining will frequently be of no avail, even though it serve for the entire removal of all pressure off the brain; for the patient cannot recover from the violence of the concussion, and never regains his senses. This is no reason, however, why the chance of the operation doing good should not be taken when there are evident symptoms of pressure. Let us, in these darkened cases, call to mind the sentiments of Pott, who says, "No man who is at all acquainted with this subject will ever venture to pronounce or promise success from the use of the trephine, even in the most apparently slight cases: he knows that honestly he cannot: it is enough that it has often been successful where and when every other means has failed. The true and just consideration is this: does the operation of perforating the cranium in such case add at all to that degree of hazard which the patient is in before it is performed? or can he in many instances do well without it? If it does add to the patient's hazard, that is certainly a very good reason for laying it aside, or for using it very cautiously; but if it does not, and the only objection made to it is, that it frequently fails of being successful, surely it cannot be right to disuse that which has often been, not only salutary, but the *causa sine qua non* of preservation, merely because it is also often unsuccessful, that is, because it is not infallible."

Giving vent to the confined blood "may produce a cure, or it may prove only a temporary relief, according to the different circumstances of different cases. The disappearance and even the alleviation of the most pressing symptoms, is undoubtedly a favourable circumstance, but is not to be depended upon as absolutely portending a good event. Either a bloody or limpid extravasation may be formed or forming between the meninges, or upon or within the brain, and may prove as certainly pernicious in future, as the more external effusion would have done had it not been discharged; or the dura mater may have been so damaged by the violence of the blow as to inflame and suppurate, and thereby destroy the patient.

If the disease lies between the dura and pia mater, mere perforation of the skull can do nothing; and, therefore, if the symptoms are pressing, there is no remedy but division of the outer of these membranes. The division of the dura mater is an operation which I have several times seen done by others, and have often done myself; I have seen it, and found it now and then successful; and, from those instances of success, am satisfied of the propriety and necessity of its being sometimes done." He next states, however, his sentiment, that wounding the dura mater is itself attended with dangerous consequences. Mr. Abernethy's opinion of such operation has already been given. It is also disapproved of by Sir Astley Cooper, who says, that if blood be not found between the dura mater and skull, do not puncture the dura mater to seek for it; which would be of no use, as the blood is coagulated, and could not escape, being seated under the pia mater, or in the brain itself.—(*Lectures, &c. p.* 289.)

If, after the removal of a portion of bone, the dura mater should present itself of a blue colour, be lifted up by blood underneath it, and bulge, as it were, into the aperture, Mr. Brodie approves of a puncture being made in that membrane; and, though he joins Pott in regarding a wound of the dura mater as a dangerous measure itself, he considers it here justified by circumstances, and supports his advice by a reference to a case in which Mr. Chevalier thus discharged a considerable quantity of blood, and the patient recovered. —(See *Med. and Physical Journ. vol.* 8, *p.* 505.) He has also adduced another instance of the success of the practice, in the hands of my friend and neighbour Mr. Ogle.

Upon the removal of a piece of bone by means of the trephine; if the operation has been performed over the part where the disease is situated, and the extravasation be of the fluid kind, and between the cranium and dura mater; such fluid, whether it be blood, water, or both, is immediately seen, and is partly discharged by such opening: if, on the other hand, the extravasation be of blood in a coagulated or grumous state, it is either loose or in some degree adherent to the dura mater; if the former of these be the case, it is either totally or partially discharged at the time of, or soon after, the operation, according to the quantity or extent of the mischief; if the latter, the perforation discovers, but does not immediately discharge it." Mr Pott then lays it down as a rule, that a large extravasation must necessarily require a more free removal of bone than a small one; and a grumous or coagulated extravasation a still more free use of the instrument.

In applying the trephine, on account of a fracture with depression, Mr. Brodie deems the removal of a small portion of bone generally sufficient; but when

blood is extravasated on the surface of the dura mater, he recommends the bone to be more freely taken away. He founds this advice on the circumstances of a case which he has recorded, where a more limited opening did not give a sufficiently ready outlet to the suppuration that ensued, and the patient died.—(See *Med. Chir. Trans. vol.* 14, *p.* 386.)

In the treatment of pressure from extravasation, Sir Astley Cooper joins the generality of surgeons in recommending free depletion, in order to prevent inflammation; the bowels, he says, are to be opened, and the patient kept very quiet. "If there be a bruise, indicating the spot at which the injury has been sustained, you may trephine *after every other means has been tried ineffectually.* If a fracture exists, and the symptoms do not yield to depletion, you will trephine to seek the extravasation."—(*Lectures, p.* 288.)

All cases of pressure on the brain are attended with hazard of inflammation of this organ and its membranes. The danger must be averted as much as possible, by applying cold washes to the head, and employing free and repeated bleeding, leeches, antimonials, saline purgatives, and other antiphlogistic means. After the depleting method has been continued some time, blisters may be applied to the head, and the cold wash omitted.

CONCUSSION OR COMMOTION OF THE BRAIN.

It is observed by Mr. Pott, that "very alarming symptoms, followed sometimes by the most fatal consequences, are found to attend great violence offered to the head; and, upon the strictest examination both of the living and the dead, neither fissure, fracture, nor extravasation of any kind can be discovered. The same symptoms, and the same event, are met with, when the head has received no injury at all *ab externo*, but has only been violently shaken; nay, when only the body or general frame has seemed to have sustained the whole violence." And he afterward remarks, that "the symptoms attending a concussion are generally in proportion to the degree of violence which the brain itself has sustained, and which, indeed, is cognizable only by the symptoms. If the concussion be very great, all sense and power of motion are immediately abolished, and death follows soon; but between this degree and that slight confusion (or stunning as it is called) which attends most violences done to the head, there are many stages." But besides the foregoing description of concussion, which seems rather to consist in a lesion of function than in any visible disorganization, Sir Astley Cooper has found the more violent degrees of it attended with laceration of the brain, and slight extravasation.—(*Lectures, &c. p.* 262.) The latter, however, are rather to be considered as compound cases than as instances of pure concussion. Mr. Brodie has observed, that the symptoms of concussion do not depend upon any such derangement of the organization of the brain as admits of being disclosed to us by dissection; yet he thinks the inference not justified, that there is really no organic change. It is difficult, he says, to conceive in what other manner concussion of the brain can operate so as to produce the effects which it is known to produce; and if we consider that the ultimate structure of the brain is on so minute a scale that our senses are incapable of detecting it, it is evident that there may be changes and alterations of structure which our senses are also incapable of detecting.—(*Brodie in Med. Chir. Trans. vol.* 14, *p.* 337.)

Mr. Abernethy, I think, has removed a good deal of the perplexity of this subject by dividing concussion into three stages. In fact, without discriminating them, the various descriptions of the symptoms, as given by different writers, cannot be at all reconciled.

"The *first* is, that state of insensibility and derangement of the bodily powers which immediately succeeds the accident. While it lasts, the patient scarcely feels any injury that may be inflicted on him. His breathing is difficult, but in general without stertor; his pulse intermits, and his extremities are cold. But such a state cannot last long; it goes off gradually, and is succeeded by another, which I consider as the *second* stage of concussion. In this, the pulse and respiration become better, and though not regularly performed, are sufficient to maintain life, and to diffuse warmth over the extreme parts of the body. The feeling of the patient is now so far restored, that he is sensible if his skin be pinched; but he lies stupid and inattentive to slight external impressions. As the effects of concussion diminish, he becomes capable of replying to questions put to him in a loud tone of voice, especially when they refer to his chief suffering at the time, as pain in the head, &c.; otherwise he answers incoherently, and as if his attention was occupied by something else. As long as the stupor remains, the inflammation of the brain seems to be moderate; but as the former abates, the latter seldom fails to increase; and this constitutes the *third* stage, which is the most important of the series of effects proceeding from concussion.

These several stages vary considerably in their degree and duration; but more or less of each will be found to take place in every instance where the brain has been violently shaken. Whether they bear any certain proportion to each other or not, I do not know. Indeed, this will depend upon such a variety of circumstances in the constitution, the injury, and the after-treatment, that it must be difficult to determine.

With regard to the treatment of concussion, it would appear that in the first stage very little can be done; and, perhaps, what little is done had better be omitted, as the brain and nerves are probably insensible to any stimulants that can be employed. From a loose and, I think, fallacious analogy between the insensibility in fainting and that which occurs in concussion, the more powerful stimulants, such as wine, brandy, and volatile alkali, are commonly had recourse to, as soon as the patient can be got to swallow. The same reasoning which led to the employment of these remedies in the *first* stage, in order to recall sensibility, has given a kind of sanction to their repetition in the *second* with a view to continue and increase it.

But here the practice becomes more pernicious and less defensible. The circumstance of the brain having so far recovered its powers as to carry on the animal functions in a degree sufficient to maintain life, is surely a strong argument that it will continue to do so, without the aid of means which probably tend to exhaust parts already weakened by the violent action they induce.

And it seems probable that these stimulating liquors will aggravate that inflammation which must sooner or later ensue."—(*Essay on Injuries of the Head, p.* 59.)

In most cases of concussion, the patient vomits after the accident. According to Mr. Brodie, sickness and vomiting are generally early symptoms, and seldom continue after the patient has recovered from the first shock of the accident.—(*Med. Chir. Trans. vol.* 14, *p.* 339.) In the beginning, a torpor exists in the intestinal canal, and considerable difficulty in procuring an evacuation; but afterward the feces are sometimes involuntarily discharged; and the bladder becomes distended, so as to require the catheter; but after a time, the urine also comes away involuntarily. There is sometimes bleeding at the nose, and a part of the blood which drops into the throat is vomited up. The pupils of the eyes are generally natural; but if changed, both are a little dilated, or sometimes only one. The state of the pupils, however, is differently represented by different writers, and my experience has taught me that it is subject to much variety. In that stage in which the sensibility of the patient is impaired, but not annihilated, "the pupils contract on exposure to light, and are sometimes more contracted than under ordinary circumstances."—(*Brodie, vol. cit. p.* 338.) According to Sir Astley Cooper, the pulse, although natural when the patient is undisturbed, scarcely ever fails to be quickened by any exertion made by the patient: and the carotids sometimes pulsate with great force; but the latter symptom is generally not noticed till after a few hours. The state of the pulse is very different, according to the stage of the disorder. In severe cases, the pulse is at first intermitting, irregular, feeble, perhaps scarcely perceptible, and the patient in a condition approaching that of syncope. Such may be his situation for several hours after the accident. When concussion proves fatal, the cause of death is imputed by Mr. Brodie to this disturbance of the action of the heart. "In general, when the patient has lain for some time in the state which has been described, a reaction of the circulating system takes place, and the pulse beats with greater strength in proportion as the failure of it was greater in the first instance. But where the shock has been unusually severe, there is no such

reaction. The pulse becomes more and more feeble, more irregular and intermittent; the extremities grow cold, and at last the action of the heart being altogether suspended, the patient expires. In some cases, even after reaction has begun to take place, it seems as if the constitution were unequal to the effort: there is another failure of the circulation, the result of which is the same as if the patient had never rallied from the beginning."—(*Brodie, in Med. Chir. Trans. vol.* 14, *p.* 341.) The mind, as Sir Astley Cooper remarks, is variously affected, according to the degree of injury which the patient has sustained. In some cases, there is a total loss of mental power; in others, the patient is capable, though with difficulty, of being roused to make a rational answer, but immediately sinks again into coma. Sometimes the memory is lost; while in other instances, it is only partially impaired. A total forgetfulness of any foreign language is a common effect of concussion. It frequently happens that the patient, when roused, will be perfectly sensible and answer questions rationally; but if left undisturbed, the mind appears to be occupied by some particular circumstance (often an incoherent one), of which he is constantly talking. Patients recollect nothing about the mode in which their accidents took place. If the injury has been occasioned by a fall from a horse, they can only remember mounting and riding to some distance, but not that the animal ran away or threw them; nor, however perfectly they may recover in other respects, do they ever have any recollection of the kind of accident. The change produced by injuries of the brain is remarked to be somewhat similar to the effects of age; the patient loses impressions of a recent date, and is sensible of those which he received in his earlier years. But, as Sir Astley correctly explains, the degree of injury sustained by the brain varies considerably in different cases. Some patients are only stunned, or deprived of sense for a moment; others recover in a few hours; some remain in a great degree insensible for fifteen or twenty days. Some recover entirely; others have afterward an imperfect memory. A partial loss of sense will be produced in the function of one eye, or deafness in one ear; and so of volition, the squinting caused by an injury of the brain being sometimes permanent. In some cases a degree of fatuity; in some, great irritability; in others, vertigo, and tendency to severe headache from the slightest excitement, will remain. In one example seen by Sir Astley Cooper, a remarkable irritability of the stomach and disposition to vomit were the permanent consequences of a concussion of the brain. In particular instances, the faculty of readily uttering the proper words for expressing ideas is lost and never regained, and wrong terms are used. Often the judgment remains enfeebled.—(*Lectures, vol.* 1, *p.* 254, *&c.*) Many of the observations in the foregoing statement coincide with the accounts given of the subject in the writings of Bichat and Desault.

The following passage, extracted from a writer who has already been of material assistance in this article, cannot be too deeply impressed on the memory of every surgical practitioner.

"To distinguish between an extravasation and commotion by the symptoms only, is frequently a very difficult matter, sometimes an impossible one. The similarity of the effects in some cases, and the very small space of time which may intervene between the going off of the one and accession of the other, render this a very nice exercise of the judgment. The first stunning or deprivation of sense, whether total or partial, may be from either, and no man can tell from which; but when these first symptoms have been removed, or have spontaneously disappeared, if such patient is again oppressed with drowsiness or stupidity, or a total or partial loss of sense, it then becomes most probable, that the first complaints were from commotion, and that the latter are from extravasation; and the greater the distance of time between the two, the greater is the probability not only that an extravasation is the cause, but that the extravasation is of the limpid kind, made gradatim, and within the brain.

When there is no reason to apprehend any other injury, and commotion seems to be the sole disease, plentiful evacuation by phlebotomy and lenient cathartics, a dark room, the most perfect quietude, and a very low regimen, are the only means in our power; and are sometimes successful."—(*Pott.*) When the patient is at all sensible, every thing likely to irritate the mind is to be avoided.—(*A. Cooper, Lectures, &c. p.* 279, *vol.* 1.)

With these means should also be associated the constant application to the head of cloths dipped in very cold water, or Schmucker's frigorific lotion. When the effects of the violence are not necessarily fatal in a very short time after the accident, the great danger which is to be guarded against is certainly inflammation of the brain. Hence the necessity of freely employing the lancet and antiphlogistic means. The discrimination which Mr. Abernethy introduced into the views of the present subject, by his division of concussion into three stages, has led also to more rational and successful practice. For, though bleeding is now generally allowed to be the great means of relief in concussion, it is not rashly practised at the beginning of many cases, when the pulse can hardly be felt, when the circulation scarcely goes on, and every action in the system is nearly annihilated. But the state of the pulse and circulation is closely watched, and the surgeon bleeds in sufficient time and quantity, to prevent in many instances that immoderate frequency and hardness which the pulse always has a tendency in these cases to assume, immediately the first shock of the accident begins to abate. "Bleeding," as Sir Astley Cooper correctly notices, "may be carried to excess. You must, in the repetition of bleeding, regulate your conduct by the symptoms; observe whether there be any hardness in your patient's pulse, and whether he complains of pain in the head, if he have still the power of complaining. Watch your patient with the greatest possible anxiety; visit him at least three times a day: and if you find any hardness of the pulse supervening after the first copious bleeding, take away a tea-cupful of blood; but do not go on bleeding him largely; for you would, by this means, reduce the strength too much, and prevent the reparative process of nature." Sir Astley admits, however, that it is frequently necessary to take away blood after the first bleeding; but he directs this to be generally done in small quantities. He acknowledges, also, that it is sometimes necessary to take away large quantities by repeated bleedings.—(*P.* 271.) The recovery of many cases which have fallen under my own observation, I have imputed to the frequent and even copious abstraction of blood, by means of the lancet, leeches, and cupping; at the same time, I know that this practice is often carried beyond all moderation, without due attention to those circumstances which I have mentioned as the proper guide.

I believe, with Mr. Abernethy and Mr. Brodie, that in the very first stage of concussion, when all the powers of life are depressed, cordials and stimulants can rarely be employed with advantage. The latter gentleman has lately offered some considerations against the method which merit attention. There are, he observes, sufficient reasons why we should regard that condition of the system which approaches to syncope, as being mostly conducive to the patient's welfare, and why we should wish to prolong rather than abridge the period of its duration. The same blow which gives rise to symptoms of concussion, he remarks, frequently occasions the rupture of some small vessels within the cranium. The same state of the system which produces an enfeebled action of the heart, is calculated to prevent the ruptured vessels from pouring out their contents; and the longer it continues, the less is the danger of internal hemorrhage. If we excite the action of the heart with wine and ammonia, we may bring on symptoms of pressure on the brain. If, on the contrary, we watch the gradual restoration of the pulse, and bleed at the proper moment in quantity sufficient to keep down the action of the heart, we may often check extravasation. Mr. Brodie also argues, that as the state of depression is followed by one of excitement, it is another strong consideration in favour of avoiding stimuli, and having recourse to bleeding in time to prevent the action of the heart from becoming too vehement.—(See *Med. Chir. Trans. vol.* 14, *p.* 377.)

With respect to emetics, I have no confidence myself in their usefulness in cases of concussion, and much doubt even their safety, especially when the disorder is complicated with extravasation (*A. Cooper, Lectures, &c. vol.* 1, *p.* 276), a point often incapable of positive decision.

Purgative an antimonial medicines should be prescribed, and a low regimen enjoined. After bleeding has been freely practised and the bowels emptied, blisters on the scalp and nape of the neck are frequently very useful in preventing or lessening the tendency to inflammation of the brain and its membranes.

As bleeding from the arm cannot be employed in young children, Sir A. Cooper recommends the exhibition of calomel, with acescent drinks, so as to purge them; and leeches, or opening the jugular vein.

For the relief of certain symptoms, frequently remaining after concussion, as pain in the head, giddiness, diminution of sight, and deafness, Sir A. Cooper directs the head to be washed with spirit of wine and water, or the use of the shower-bath. Sometimes he orders the ung. canthar. to be rubbed on the head, and pil. hydrarg. and extr. colocynth. to be given. In cases of nervous debility of an organ, electricity is sometimes useful; and occasionally, in long-continued pains of the head, he forms an issue in the scalp, benefit sometimes resulting even from slight exfoliations.—(*Lectures, vol.* 1, *p.* 280.) These measures are infinitely more prudent than the old custom of trephining.

I cannot conclude this article without adverting to the great propensity to relapse, after patients have long appeared out of every danger from wounds of the head, the bad symptoms sometimes coming on again, and proving fatal many years after the original injury, as is strongly exemplified in a case related in a work of high character.—(See *Schmucker's Vermischte Schriften, b.* 1, *p.* 247.)

[In the third number of the *Amer. Jour. of the Med. and Phys. Sciences*, Professor Sewall, of Washington city, has reported two cases of fracture of the cranium, with *loss of a portion of the substance of the brain.* The wound in one of them was inflicted with a spade, which penetrated through the dura mater and into the medullary portion of the brain. The antiphlogistic treatment was relied upon from the commencement, and during the suppuration which followed: the brain itself protruded and sloughed away, and subsequently portions of it were removed by the spatula. This patient, nevertheless, recovered entirely in six weeks after the accident.

Professor Dudley has also written a valuable paper on injuries of the head, which may be found in the first number of the *Transylvania Journal of Medicine.* He reports a number of cases of epilepsy occurring after injuries of the cranium, which he has cured by trephining. In confirmation of his views I may here refer to a case published in the 5th vol. of the *N. Y. Med. and Phys. Journal*, in which epilepsy, originating from depression of bone, was cured by trephining, by Dr. David L. Rogers, of this city.—*Reese.*]

HEMERALOPIA. According to M. Dujardin, this term is derived from ἡμέρα, the day, ἀλαὸς, blind, and ὤψ, the eye, and its right signification is therefore inferred to be *diurna cœcitudo*, or *day-blindness.*—(See *Journal de Méd. t.* 19, *p.* 348.) In the same sense, Dr. Hillary (*Obs. on the Diseases of Barbadoes, p.* 298, *edit.* 2) and Dr. Heberden (*Med. Trans. vol.* 1, *art.* 5) have employed the term.

Hemeralopia, then, which is of very rare occurrence, stands in opposition to the *nyctalopia* of the ancients, or *night-blindness.* Numerous modern writers, however, have used these terms in the contrary sense; considering the hemeralopia as denoting sight during the day, and blindness in the night; and nyctalopia as expressing night-seeing, owl-sight, as the French call it, and blindness during the daytime.

Hemeralopia, in the meaning of day-blindness, is a very uncommon affection. Dr. Hillary never met with but two examples. He mentions a report, however, that there are a people in Siam, in the East Indies, and also in Africa, who are subject to the disease of being blind in the daytime, and seeing well by night.—(*Med. Univ. Hist. vol.* 7.)

According to Sauvages, hemeralopia (in his nomenclature called *amblyopia crepuscularis*) was in some degree epidemic in the neighbourhood of Montpellier, in the villages in damp situations, adjoining rivers, and it particularly affected the soldiers, who slept in the open damp air. They were cured, he says, by blistering, together with emetics and cathartics, and other evacuants.—(*Nosol. Method. class* 6, *gen.* 3, *spec.* 1.)

See some ingenious observations on the subject in *Dr. Rees's Cyclopædia, art. Hemeralopia*, and by Mr. Bampfield, in *Med. Chir. Trans. vol.* 5, *p.* 34, *&c.*

Scarpa, with the generality of modern writers, has considered hemeralopia as an affection, in which the patient sees very well in the day, but not in the nighttime.

The abolition of eyesight by night (observes Mr. Bampfield) has occurred in all ages, and is a common disease of seamen in the East and West Indies, Mediterranean, and in all hot and tropical countries and latitudes, and affects more or less the natives likewise of those regions of the globe. It also occurs frequently among soldiers in the East and West Indies; but he has been informed that it is by no means so prevalent among them as sailors. It is not an uncommon complaint of the Lascars employed in the East India Company's ships trading between India and Europe. It has very rarely indeed affected the officers of his Majesty's or of the East India Company's ships. Celsus has remarked, that women and virgins, whose menstrual returns are regular, are exempt from this disease (*lib.* 6, *cap.* 6); and it may be observed, that the inhabitants of cold latitudes are less subject to hemeralopia in their own climate, than the natives of tropical countries are in theirs; but more so, when they visit the tropics.—(*Med. Chir. Trans. vol.* 5, *p.* 38.)

"*Hemeralopia*, or *nocturnal blindness* (says Scarpa), is properly nothing but a kind of imperfect periodical amaurosis, most commonly sympathetic with the stomach. Its paroxysms come on towards the evening, and

disappear in the morning. The disease is endemic in some countries, and epidemic at certain seasons of the year in others.

At sunset, objects appear to persons affected with the complaint, as if covered with an ash-coloured veil, which gradually changes into a dense cloud, which intervenes between the eyes and surrounding objects. Patients with hemeralopia have the pupil, both in the day and night-time, more dilated and less moveable than it usually is in healthy eyes. The majority of them, however, have the pupil more or less moveable in the daytime, and always expanded and motionless at night. When brought into a room faintly lighted by a candle, where all the bystanders can see tolerably well, they cannot discern at all, or in a very feeble manner, scarcely any one object: or they only find themselves able to distinguish light from darkness: and at moonlight their sight is still worse. At daybreak they recover their sight, which continues perfect all the rest of the day till sunset."—(*Cap.* 19, *p.* 322, *ed.* 8*vo.*)

According to Mr. Bampfield, the disease always affects both eyes at the same time. "In general (says this gentleman), the nocturnal blindness is at first partial, the patient is enabled to see objects a short time after sunset, and perhaps will be able to see a little by clear moonlight. At this period of the complaint, he is capable of seeing distinctly by bright candlelight. The nocturnal sight, however, becomes daily more impaired and imperfect; and, after a few days, the patient is unable to discriminate the largest objects after sunset, or by moonlight, &c.; and finally, after a longer lapse of time, he cannot perceive any object distinctly by the brightest candlelight. If the patient is permitted to remain in this state of disease, the sight will become weak by daylight, the rays of the sun will be too powerful to be endured, whether they are direct or reflected; lippitude is sometimes induced; myopism, or shortness of sight succeeds; and in progress of time vision becomes so impaired and imperfect, that apprehensions of a total loss of sight are entertained; and this dreadful consequence has been known to ensue, where the complaint has been totally neglected, or left to nature, or where ineffectual remedies have been employed."—(*Bontius*, *p.* 73.)

"It has been remarked by some, that the patients are capable of seeing distinctly, at all periods of the complaint, with the aid of a strong artificial light; but in *bad* cases of hemeralopia, in my practice, the patients positively denied the existence of the sense of distinct sight by very clear candlelight."—(*Bampfield*, *in Medico-Chir. Trans. vol.* 5, *p.* 39, 40.)

The duration of the disease, when left to itself, is generally from two weeks to three or six months. Experience has not proved that the disposition to the complaint depends upon any particular colour of the iris, as several writers have conjectured; nor upon the largeness of the eyes, as alleged by Hippocrates.—(*Lib.* 6, *sec.* 7.)

In idiopathic cases, the health does not in general suffer, and, except in the worst stage, the eye is not altered in appearance. But in cases of long duration the pupil, according to Mr. Bampfield, "is often contracted, and the eyes and actions of the patient evince marks of painful irritation, if the eyes are exposed to a vivid light, or if he looks upwards. But if they meet the direct rays of the sun, which in the tropics are always powerful, or a strong glaring reflection of them, pain and temporary blindness are induced, from which the patient recovers by closing his eyelids for a time to exclude the rays of light, and retiring to the shade. The pupil of the eye is considerably dilated both by day and night, in the proportion of about one case in twelve, and at night the pupil is often dilated, and does not perform its expansions and contractions when exposed to the moon or artificial light. The cases attended with dilated pupil were generally those of long duration, &c.

"Europeans, who have been once affected with hemeralopia in tropical climates, are particularly liable to a recurrence of this disease as long as they remain in them."—(*Bampfield*, *op. cit. p.* 42, 43.)

In two examples, described by Dr. Andrew Smith, the pupils were observed to contract and dilate regularly in the daytime, according to the quantity of light; but after sunset they seemed a little more dilated than natural, and contracted but sluggishly upon exposure to light, while the eyes themselves seemed devoid of their usual energy and vivacity.—(See *Edinb Med. and Surgical Journ. No.* 74, *p.* 22.)

The remote causes of idiopathic hemeralopia are not well ascertained. Sleeping with the face exposed to the brilliancy of daylight, the vivid reflection of the sun's rays from the sandy shores of hot countries, and bright moonlight, have been enumerated as causes. Dr. Pye thinks the disorder intermittent.—(*Med. Obs. and Inquiries, vol.* 1, *art.* 13.) But, as Mr. Bampfield properly observes, though the complaint is certainly periodical, there is nothing in its character tending to prove that it is influenced by the same causes as intermittent fever. The latter gentleman conjectures, "that too much light suddenly transmitted to the retina, or for a long period acting on it, may afterward render it unsusceptible of being stimulated to action by the weaker or smaller quantities of light transmitted to it by night."—(*P.* 44.) The same sentiment is adopted by Dr. Smith.—(*Edinb. Med. Journ. No.* 74, *p.* 23.) Among other objections to this explanation, however, it might be remarked, that the patients do not always see, though the light be good; and Mr. Bampfield's own "patients positively denied the existence of distinct sight by very clear candlelight." Besides, if the disease were entirely caused by the sudden or long operation of vivid light, one would conclude that all persons subjected to that cause ought to have the effect produced, which is far from being the case.

When the tongue is white, and the patient has headache and bilious complaints, M. Lassus thinks the cause of the disease is in the stomach and primæ viæ. The same author likewise states, that hemeralopia attacks debilitated persons subject to catarrhal affections, residing in damp situations, and living on indigestible food. From the combination of such causes (says he) the disorder was epidemic in the vicinity of Montpellier (*Sauvage*, *Nosolog. M thod. t.* 2, *p.* 732); at Belle-Isle sur Mer. (*Recueil d'Observ. de Médecine des Hôpitaux Militaires*, *par Richard*, *t.* 2, *p.* 573); and hence it is endemic in watery situations where the nights are cold and damp. They who expose themselves to this humidity (says M. Lassus), or who navigate along the eastern coasts of Africa, who traverse the Mozambique channel, or sail along the coasts of Malabar and Coromandel, are sometimes attacked by it.—(See *Pathologie Chir. t.* 2, *p.* 542, 543.) Hemeralopia sometimes occurs as a symptom of the scurvy. This fact was noticed by Mr. Telford, in Sir G. Blane's *Treatise on Diseases of Seamen*, and it is likewise confirmed by Mr. Bampfield, who remarks that hemeralopia should be referred to the same causes as scurvy, "when the subject of it has for a long period subsisted on a salted diet at sea, &c., and if any other scorbutic symptom be present, such as spongy gums, ecchymoses, saline smell of the secretions, ulcers, with liver-like fungus, &c."—(*Medico-Chir. Trans. vol.* 5, *p.* 45.)

This disease, according to Scarpa, may commonly be completely cured, and oftentimes in a very short time, by treating it on the same plan by which the imperfect amaurosis is remedied (see *Amaurosis*); viz. by employing emetics, the resolvent powders and pills, and a blister on the nape of the neck; and topically, the vapours of ammonia; lastly, by prescribing towards the end of the treatment bark conjoined with valerian. In cases in which the disease has been preceded by plethora and suppressed perspiration, bleeding and sudorifics are also indicated.—(*Cap.* 19, *p.* 322. 333.)

Scarpa supports this statement by the relation of three cases in which he cured the disease by such treatment. These patients were all unhealthy, and evidently labouring under disorder of the gastric organs.

One hundred cases, however, of idiopathic, and two hundred of symptomatic hemeralopia, occurred in the practice of Mr. Bampfield in different parts of the globe, but chiefly in the East Indies. All these cases perpectly recovered: and hence we may infer that under proper treatment a favourable prognosis may always be given.

Celsus has stated that persons who have been for some time affected with amaurosis, have regained their sight on being attacked by a diarrhœa. This seems to Scarpa to be corroborated by the case related by Dr Pye.—(*Med. Obs. and Inq. vol.* 1.) Scarpa entertains no doubt that many similar facts, showing the influence of what he terms morbific gastric stimuli over the organ of sight, might be found in the records of medicine, and proving the great utility of a spontaneous

looseness of the bowels in the cure of imperfect amaurosis.

But, says Scarpa, even if such examples of incomplete amaurosis being dissipated in consequence of spontaneous vomiting or copious evacuations from the bowels, produced entirely by nature, were rare, and noticed by few, we now have many cases evincing the successful cure of this disease by means of such evacuations artificially produced by emetics and purgative medicines. Of this the accurate observations of Schmucker and Richter furnish us with numerous satisfactory proofs, and it is added, that our confidence in the above method of curing the imperfect and periodical amaurosis must increase when we take notice that the most respectable practitioners of past times have, in the majority of cases, cured this disease only by means of emetics and opening medicines, though in their writings they may have imputed the success of the treatment to other causes, or the efficacy of other remedies which were also prescribed.

Scarpa, after several valuable remarks on amaurosis in general, refers to the *Mercure de France*, for February, 1756, where there is an account of the cures performed by Fournier, by means of bleeding and emetics.

Night-blindness is sometimes congenital, and therefore constitutional, and altogether beyond the reach of any curative measure. It is said sometimes to be hereditary, and the writer of the article *Nyctalopia* in Dr. Rees's Cyclopædia was acquainted with an instance in which it occurred to two children of the same family. A case of congenital nyctalopia, which had continued many years without change, and independently of any disease, is related by Dr. Parham.—(See *Med. Obs. and Inquiries*, *vol.* 1, *p.* 122, *note.*)

Pellier (*Recueil de Mém. et Obs. sur l'Œil*, *obs.* 132) cured hemeralopia by repeated doses of tartar-emetic, a seton in the nape of the neck, and cooling, aperient beverages.

The method of treatment which Mr. Bampfield adopted is certainly quite simple. "A succession of blisters to the temples (says he), of the size of a crown or half-crown piece, applied tolerably close to the external canthus of the eye, has succeeded in every case of idiopathic hemeralopia which I have seen, &c. The first application of blisters commonly enables the patient to see dimly by candlelight, or perceive objects without the power of discriminating what they are. In some slight cases which admitted of easy cure, the first application succeeded perfectly. The second application of blisters commonly enables the patient to see by candlelight distinctly, perhaps, by bright moonlight, and even half an hour after sunset, or the sight is restored for short periods during the night, and is again abolished. The second application very often effects a perfect recovery. The third, fourth, or fifth applications in succession generally produce a complete recovery where the first or second have failed; but some rare instances of very obstinate hemeralopia have required even ten successive blisters to each temple; or instead of using them in succession, a perpetual vesicatory has been formed on each temple, and maintained until a cure has been accomplished, an event which has generally followed in a fortnight."—(*Bampfield in Medico-Chir. Trans. vol.* 5, *p.* 47, 48.) In some cases, shades over the eyes were worn during the treatment, and a certain time after the cure. The patients were also often directed to bathe their eyes with cold water two or three times a day.

Mr. Bampfield knew of some instances in which electricity was successfully employed as a topical stimulus to the eye. He also informs us that a spontaneous cure sometimes followed the eruption of biles on the head or face, or the formation of abscesses on these parts, or in the ears.

Although blisters will generally effect a cure, there were particular cases in which Mr. Bampfield administered cathartics, such as calomel and the neutral salts. In these examples the patient had bilious complaints, indicated by a yellow state of the tongue and skin, headache, and pain about the præcordia; or symptoms of indigestion; white tongue, loss of appetite, pain and flatulence of the stomach, &c. With blisters and aperient medicines Mr. Lawrence sometimes combines cupping on the temples or nape of the neck.

The patients treated by Dr. Smith were put into a ward moderately lighted, and their bowels emptied by a gentle cathartic. A blister was then applied to each temple, and kept open with savin cerate. A little of a solution of the oxymuriate of mercury, in the proportion of two grains to an ounce of water, was dropped into the eyes twice a day. The purgatives were repeated on the third day, and the quantity of light to which the patients were exposed was afterward gradually increased.—(See *Edinb. Med. Journ. No.* 74, *p.* 24.)

In the scorbutic hemeralopia, the application of blisters is to be deferred, until the state of the constitution is amended by giving lemon and lime-juice, and fresh animal and vegetable food; because the hemeralopia often gradually ceases as the scurvy is cured; and before this last event the blister might produce a scorbutic ulcer. Mr. Bampfield estimates that about one-third of the cases of scorbutic hemeralopia resist the efficacy of the antiscorbutic regimen and medicines; and consequently must ultimately be treated as idiopathic cases.

The frequent recurrence of this disease, during the patient's continuance in a tropical or hot climate, naturally suggests the propriety of recommending him to return to his native climate, by which change the tendency to a relapse is in general completely removed.—(*Bampfield, in Medico-Chir. Trans. vol.* 5, *p.* 53.)

HEMIOPIA. (From ἡμισυς, half, and ὤψ, the eye.) A certain disorder of the eye, in which the patient cannot see the whole of any object which he is looking at, but only a part of it. Sometimes he sees the middle, but not the circumference; sometimes the circumference, but not the centre; while on other occasions, it is only the upper or lower half which is discerned. Sometimes objects are seen thus imperfectly, whether distant or near; sometimes only when they are near, and not at a great distance.

The causes of hemiopia are divided by Richter into four kinds.

To the first belong opacities of the cornea and crystalline lens, especially such as destroy the transparency of only a certain portion of these parts.

The cure of this species of hemiopia depends upon the removal of the partial opacity from which it originates.—(See *Cataract*, and *Cornea*, *Opacities of.*)

Under certain circumstances, persons whose upper eyelids cannot be properly raised, are affected with hemiopia. They can only discern the lower half of an object which is near and of large size, unless they go farther from it, draw their heads backwards, or turn their eyes downwards. The pupil, in particular instances, becomes drawn away from the middle of the iris. This may also be a cause of hemiopia: it is a case that does not admit of a cure. The affection may likewise proceed from a separation of the iris from the margin of the cornea by external violence or other causes. Here the cure is equally impracticable.

The foregoing species of hemiopia are merely effects

of other diseases. The fourth and last kind is the most important, being generally regarded as an independent disorder. Sometimes it appears rather to be the effect of a sudden and transient irritation, producing a morbid sensibility in the optic nerve.

The causes of this sort of case, if we can credit Richter, are mostly seated in the abdominal viscera. When the affection is more durable, forming what has been termed *amaurosis dimidiata*, the same treatment is indicated as in *Amaurosis*, in which, indeed, it often terminates.—(*Richter, Anfangsgr. der Wundarzn. b.* 3, *kap.* 17.)

HEMORRHAGE. (From αἷμα, blood, and ῥήγνυμι, to break out.) *Bleeding.*

This is doubtless one of the most important subjects in surgery. The fear of hemorrhage retarded the improvement of our profession for ages: the ancients, ignorant how to stop bleeding, were afraid to cut out the most trivial tumour, or they did so with terror. They generally performed slowly and imperfectly, by means of burning irons or ligatures, the same operations which the moderns execute quickly and safely with a knife. If the old surgeons ventured to amputate a limb, they only did so after it had mortified, by dividing the dead parts; and so great was their apprehension of hemorrhage, that they only dared to cut parts which could no longer bleed.—(*John Bell's Principles of Surgery, vol.* 1, *p.* 142.) But not only as a consequence of surgery is hemorrhage to be feared; it is also one of the most alarming accidents which surgery is called upon to relieve. "*Un sentiment naturel attache à l'idée de perdre son sang; un terreur machinale, dont l'enfant qui commence à parler, et l'homme le plus décidé, sont également susceptibles. On ne peut point dire, que cette peur soit chimérique. Si l'on comptoit ceux, qui perdent la vie dans une bataille, on verroit, que les trois quarts ont péri par quelque hemorrhagie; et dans les grandes opérations de chirurgie cet accident est presque toujours le plus formidable.*"—(*Morand, Mém. de l'Acad. Royale de Chirurgie, vol.* 5, 8*vo.*)

As the blood circulates in the arteries with much greater impetus and rapidity than in the veins, it necessarily follows, that their wounds are generally attended with much more hemorrhage than those of the latter vessels, and that such hemorrhage is more difficult to suppress. However, as the blood also flows through veins of great magnitude with much velocity, bleedings from them are frequently highly dangerous, and sometimes unavoidably fatal. When an artery is wounded the blood is of a bright scarlet colour, and gushes from the vessel *per saltum*, in a very rapid manner. The blood issues from a vein in an even, unbroken stream, and is of a dark purple red colour. It is of great practical use to remember these distinguishing differences between arterial and venous hemorrhage, because, though in both cases the oozing of blood may be equal in quantity, yet, in the latter instance, the surgeon is often justified in bringing the sides of a wound together, without taking farther means to suppress the bleeding, while it would not be proper to adopt the same conduct were there an equal discharge of arterial blood.

Dr. Jones has favoured the world with a matchless work on the present subject; and as one grand object of this Dictionary is to present a careful account of the principal modern improvements in surgical science, I shall first endeavour to make the reader acquainted with the more accurate doctrines first promulgated by this gentleman relative to the subject of hemorrhage. Afterward, the surgical means to be practised in different cases will be considered.

The sides of the arteries are divisible into three coats. The *internal one* is extremely thin and smooth. It is elastic and firm (considering its delicate structure) in the longitudinal direction, *but so weak in the circular as to be very easily torn by the slightest force applied in that direction.* Its diseases show that it is vascular, and it is also probably sensible.

The *middle coat* is the thickest and is composed of muscular fibres all arranged in a circular manner; they differ, however, from common muscular fibres in being more elastic, by which they tend to keep a dead artery open, and of a cylindrical form. As this middle coat has no longitudinal fibres, *the circular fibres are held together by a slender connexion, which yields readily to any force applied in the circumference of the artery.*

The *external coat* is remarkable for its whiteness, density, and great elasticity. *When an artery is surrounded with a tight ligature, its middle and internal coats are as completely divided by it as they could be by a knife, while the external coat remains entire.*

Besides these proper coats, all the arteries in their natural situations are connected by means of fine cellular substance, with surrounding membranous sheaths. *If an artery be divided, the divided parts, owing to their elasticity, recede from each other, and the length of the cellular substance connecting the artery with the sheath admits of its retracting a certain way within the sheath.*

Another important fact is: *that when an artery is divided, its truncated extremities contract in a greater or less degree, and the contraction is generally, if not always, permanent.*

Arteries are furnished with arteries, veins, absorbents and nerves; *a structure which makes them susceptible of every change to which living parts are subjected in common; enables them to inflame when injured, and to pour out coagulable lymph, by which the injury is repaired or the tube permanently closed.*—(See *Jones on Hemorrhage.*)

Petit the surgeon, in 1731, first endeavoured to explain the means which nature employs for the suppression of hemorrhage. He thought that bleeding from a divided artery is stopped by the formation of a coagulum of blood, which is situated partly *within* and partly *without* the vessel. The clot, he says, afterward adheres to the inside of the artery, to its orifice, and to the surrounding parts; and he adds, that when hemorrhage is stopped by a ligature, a coagulum is formed above the ligature, which only differs in shape from the one which takes place when no ligature is employed. His theory leads him to recommend compression for the support of the coagulum.

In 1736, Morand published additional interesting remarks. He allowed, that a coagulum had some effect in stopping hemorrhage, but contended that a corrugation, or plaiting of the circular fibres of the artery which diminish its canal, and a shortening and consequent thickening of its *longitudinal ones*, which nearly rendered it impervious, had some share in the process. He thought that the cavity of an artery might be obliterated, by the puckering or corrugation, when *circular pressure like that of a ligature was made.*

Morand erred chiefly in his mode of explanation, and in his belief in the existence of longitudinal fibres, which no modern anatomists admit; for the *contraction* and *retraction* of divided arteries are indisputable facts, and as Dr. Jones remarks, this does not affect the truth of his general conclusion, *that the change produced on a divided artery, contributes with the coagulum to stop the flow of blood.*

Mr. S. Sharp (*2d edit. of Operations of Surgery*, 1739) supported the same doctrine. "The blood-vessels, immediately upon their division, bleed freely, and continue bleeding till they are either stopped by art, or at length contracting and withdrawing themselves into the wound, their extremities are shut up by coagulated blood."

Pouteau (*Mélanges de Chirurgie*, 1760) denied that a coagulum is always found after an artery is divided; and when it is, he thought it only a feeble subsidiary means towards the suppression of hemorrhage. He contended that the retraction of the artery had not been demonstrated, and could not be more effectual than a coagulum. His theory was, that the swelling of the cellular membrane at the circumference of the cut extremity of the artery forms the principal impediment to the flow of blood; and that a ligature is useful in promoting a more immediate and extensive induration of the cellular substance.

Gooch, White, Aikin, and Kirkland, all oppose Petit's doctrine of coagulum. The first blends some of Pouteau's theory with his own, by observing, that "when a small artery is totally divided, its retraction may bring it under the surrounding parts, and with the natural contraction of the diameter of its mouth, assisted by the compressive power of those parts, increased by their growing tumid, the efflux of blood may be stopped."

White was convinced, from what Gooch had suggested and Kirkland confirmed, that the arteries, by their natural contraction, coalesce as far as their first ramification.

Dr. Jones admits, that an artery contracts after it has been divided, and his experiments authorize him to say, that the contraction of an artery is an important means, but certainly not the only nor even the chief means, by which hemorrhage is stopped. When the artery is above a certain size, the impetuous flow of blood through the wound of the artery would resist the contraction of the vessel in such a degree, that the consequences would be fatal in almost every instance, were it not for the formation of coagulum.

Mr. J. Bell thinks, that when hemorrhage stops of its own accord, it is neither from the retraction of an artery, nor the constriction of its fibres, nor the formation of clots, but by the cellular substance which surrounds the artery being injected with blood.

We must refer the reader to Dr. Jones's work for a complete exposure of the inconsistencies and absurdities in Mr. Bell's account of his own theory.—(See *p.* 25, *&c.*)

Dr. Jones concludes his criticisms on Mr. Bell with observing, that if this gentleman really mean to confine his doctrine of the natural mean of suppressing hemorrhage to the injection of the cellular substance round the artery with blood, he dwells improperly on one of the attendant circumstances, to the exclusion of the retraction and contraction of an artery, and the formation of a distinct clot, all primary parts of the process.

The blood, besides filling the cellular substance round the artery, also fills the cellular substance at the mouth of the artery in a particular manner; for the divided vessel, by its retraction within its cellular sheath, leaves a space of a determinate form, which, when all the circumstances necessary for the suppression of hemorrhage operate, is gradually filled up by a distinct clot.—(*Jones.*)

MEANS OF NATURE IN STOPPING BLEEDING FROM DIVIDED ARTERIES.

Dr. Jones has given a faithful and accurate detail of a series of experiments on animals, which demonstrate "that the blood, the action, and even the structure of the arteries, their sheath, and the cellular substance connecting them with it," are concerned in stopping bleeding from a divided artery of moderate size in the following manner: "An impetuous flow of blood, a sudden and forcible retraction of the artery within its sheath, and a slight contraction of its extremity, are the immediate and almost simultaneous effects of its division. The natural impulse, however, with which the blood is driven on in some measure counteracts the retraction, and resists the contraction of the artery. The blood is effused into the cellular substance, between the artery and its sheath, and passing through that canal of the sheath, which had been formed by the retraction of the artery, flows freely externally, or is extravasated into the surrounding cellular membrane, in proportion to the open or confined state of the wound. The retracting artery leaves the internal surface of the sheath uneven, by lacerating or stretching the cellular fibres that connected them. These fibres entangle the blood as it flows, and thus the foundation is laid for the formation of a coagulum at the mouth of the artery, and which appears to be completed by the blood as it passes through this canal of the sheath, gradually adhering and coagulating around its internal surface, till it completely fills it up from the circumference to the centre.—(*Jones, p.* 53.)

The effusion of blood into the surrounding cellular membrane, and between the artery and its sheath; but in particular the diminished force of the circulation from loss of blood, and the speedy coagulation of this fluid under these circumstances, most essentially contribute, says Dr. Jones, to the desirable effect.

It appears then, that a coagulum, which Dr. Jones calls the *external* one, situated at the mouth of the artery and within its sheath, forms the first complete obstacle to the continuance of bleeding; and though it seems externally like a continuation of the artery, yet, on slitting open this vessel, its termination can be plainly observed, with the coagulum shutting up its mouth, and contained in its sheath.

No collateral branch being very near the impervious mouth of the artery, the blood just within it is at rest, and usually forms a slender conical coagulum, which neither fills up the canal of the artery nor adheres to its sides, except by a small portion of the circumference of its base near the extremity of the vessel. This coagulum is distinct from the former, and what Dr. Jones calls the *internal* one.

The cut end of the artery next inflames, and the vasa vasorum pour out lymph, which fills up the extremity of the artery, is situated between the internal and external coagula, and is somewhat intermingled with them, or adheres to them, and is firmly united all round to the internal coat of the vessel. Dr. Jones farther states, that the permanent suppression of hemorrhage chiefly depends on this coagulum of lymph; but that the end of the artery is also secured by a gradual contraction which it undergoes, and by an effusion of lymph between its tunics, and into the surrounding cellular substance; whereby these parts become thickened, and so incorporated with each other, that one cannot be discerned from the other. Should the wound in the integuments not heal by the first intention, the coagulating lymph, soon effused, attaches the artery firmly to the subjacent and lateral parts, gives it a new covering, and entirely excludes it from the outward wound.

The same circumstances are also remarkable in the portion of the vessel most remote from the heart. Its orifice, however, is usually more contracted, and its external coagulum smaller, than the one which attaches itself to the other cut end of the artery.—(*Jones on Hemorrhage, p.* 56.)

The impervious extremity of the artery no longer allowing blood to circulate through it, the portion which lies between it and the first lateral branch gradually contracts, till its cavity is completely obliterated and its tunics assume a ligamentous appearance. In a few days the external coagulum, which in the first instance stopped the hemorrhage, is absorbed, and the coagulating lymph effused around it, and by which the parts were thickened, is gradually removed, so that they resume again their cellular texture

At a still later period the ligamentous portion is reduced to a filamentous state, so that the artery is, as it were, completely annihilated from its cut end to the first lateral branch; but long before this final change is accomplished, the inosculating branches have become considerably enlarged, so as to establish a free communication between the disunited parts of the main artery.

When an artery has been divided *at some distance from a lateral branch*, three coagula are formed; one of blood externally, which shuts up its mouth; one of lymph, just within the extremity of its canal; and one of blood within its cavity and contiguous to that of lymph. But *when the artery has been divided near a lateral branch, no internal coagulum of blood is formed.* —(*Jones, p.* 63.)

The external coagulum is always formed when the divided artery is left to nature; not so, however, if art interfere, for under the application of the ligature it can never form. If agaric, lycoperdon, or sponge be used, its formation is doubtful, depending entirely upon the degree of pressure that is used; but the internal coagulum of blood will be equally formed, whether the treatment be left to art or nature, if no collateral branch be near the truncated extremity of the artery; and lastly, effused lymph, which, when in sufficient quantity, forms a distinct coagulum just at the mouth of the artery, will be always found, if the hemorrhage be permanently suppressed.—(*Jones, p.* 74.)

MEANS WHICH NATURE EMPLOYS FOR SUPPRESSING THE HEMORRHAGE FROM PUNCTURED OR PARTIALLY DIVIDED ARTERIES.

The suppression of hemorrhage by the natural means is sometimes more easily accomplished when an artery is completely divided, than when merely punctured or partially divided. Completely dividing a wounded artery was one means practised by the ancients for the stoppage of hemorrhage: the moderns frequently do the same thing when bleeding from the temporal artery proves troublesome.

Dr. Jones has related many experiments highly worthy of perusal, and which were undertaken to investigate the present part of the subject of hemorrhage. He candidly acknowledges, however, that in regard to the temporary means by which the bleeding from a punctured artery is stopped, he has but little to add to what Petit has explained in his third publication on hemorrhage.—(*Mém de l'Acad. des Sciences*, 1735.) The blood is effused into the cellular substance, between the artery and its sheath, for some distance both

above and below the wounded part; and when the parts are examined a short time after the hemorrhage has completely stopped, we find a stratum of coagulated blood between the artery and its sheath, extending from a few inches below the wounded part to two or three inches above it, and somewhat thicker or more prominent over the wounded part than elsewhere.

Hence, rather than say that the hemorrhage is stopped by a coagulum, it is more correct to say, that it is stopped by a thick lamina of coagulated blood, which, though somewhat thicker at the wounded part, is perfectly continuous with the coagulated blood lying between the artery and its sheath.—(*Jones, p.* 113.)

When an artery is punctured, the immediate hemorrhage, by filling up the space between the artery and its sheath with blood, and consequently distending the sheath, alters the relative situation of the puncture in the sheath to that in the artery, so that they are not exactly opposite to each other; and by this means a layer of blood is confined by the sheath over the puncture in the artery, and by coagulating there prevents any farther effusion of blood.

But this coagulated blood, like the external coagulum of a divided artery, affords only a temporary barrier to the hemorrhage: its permanent suppression is effected by a process of reparation or of obliteration.

Dr. Jones's experiments prove, that an artery, if wounded only to a moderate extent, is capable of reuniting and healing so completely, that after a certain time the cicatrization cannot be discovered, either on its internal or external surface; and that even oblique and transverse wounds (which gape most), when they do not open the artery to a greater extent than one-fourth of its circumference, are also filled up and healed by an effusion of coagulating lymph from their inflamed lips, so as to occasion but little or no obstruction to the canal of the artery. The utmost magnitude of a wound, which will still allow the continuity of the canal to be preserved, is difficult to be learned; for when the wound is large, but yet capable of being united, such a quantity of coagulating lymph is poured out, that the canal of the vessel at the wounded part is more or less filled up by it. And when the wound is still larger, the vessel soon becomes either torn or ulcerated completely across, by which its complete division is accomplished.

Beclard made a series of experiments upon dogs, whose arteries are said not to differ much from those of man, though *the impulse of the heart is not so strong, and the blood is more coagulable;* two circumstances which should be duly considered in applying any of the inferences drawn from such experiments to the human subject. "In his first experiment he pricked the femoral artery with a needle; the blood flowed, but soon stopped. On removing the coagulum it again flowed, but in a smaller stream; it gradually ceased to bleed, and finally stopped, though the coagulum was again scraped off. On examination of the artery no trace of the cicatrix was found. Several similar experiments had the same result. In experiment 4, he denuded the femoral artery, and made a longitudinal cut in it from two to three lines. The lips of the wound were seen in contact during the diastole of the ventricle, and to be separated by a jet of blood during the systole. The blood was stopped by a coagulum; this was removed twice, and each time the blood flowed in a diminished stream, but the animal died. In experiment 6, he made the same incision, but did not detach the sheath from the artery, and the wound was left to nature. The hemorrhage was not great; there was an infiltration of blood into the sheath, the size of an almond, which at the end of some days began to diminish, and disappeared in two or three weeks. On the limb being examined, fifteen days afterward, a little white ridge was found adhering firmly to the artery and to the sheath, and completely closing the wound. In the interior, there was a depressed longitudinal cicatrix of the breadth of the fifth of a line. *The canal was regular and pervious* through its whole extent.

In experiments 7, 8, 9, he made transverse incisions of $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{3}{4}$ of the circumference of the femoral artery *separated from its sheath:* all the animals died. In experiment 10, he made a transverse incision through $\frac{1}{4}$ of the circumference, *without disturbing the sheath.* The bleeding was stopped by a coagulum, but on the animal moving it again flowed, and the dog died. But in the next experiment of the same kind the blood was stopped by a coagulum, and the artery was closed by nearly the same process as in the 6th experiment. So completely was the cure at the end of six weeks that the external part of the artery did not show any mark of a wound, and the cicatrix was scarcely observable on the interior surface. In his 12th experiment he cut one-half of the circumference: the animal died; and so did it in several similar experiments. In experiment 13, he cut $\frac{3}{4}$ of the circumference: after the animal was much reduced the bleeding ceased, and the artery was closed in the same manner that it is when the section is complete.

From these experiments he concludes wounds of the arteries of dogs are cured by nature when they are only occasioned by a puncture, or a longitudinal incision, whether the artery be denuded or not; but when arising from transverse incisions they are always mortal if the artery be laid bare. If the artery retain its sheath, and the wound be $\frac{1}{4}$ or $\frac{3}{4}$ of the circumference, it may be cured by the efforts of nature; but it is always fatal if $\frac{1}{2}$ of it be cut through.—(See *Quarterly Journ. of Foreign Medicine and Surgery, vol.* 1, *p.* 26.) The inferences respecting the curability of a wound extending through $\frac{3}{4}$ of the circumference, and the incurability of one that affects only $\frac{1}{2}$ of the circumference of the vessel, I should presume must require farther examination, notwithstanding an accidental faintness produced by the sudden loss of blood in the first instance may have been the means of saving one or two of the animals on which Beclard made his experiments.

This author thinks it probable that a puncture, or longitudinal incision, in the artery of a man may be cured by nature; but that a transverse wound never cicatrizes properly, as the clot becomes displaced, or, if a cicatrix be formed, it will be distended and torn.

One fact made out by the same professor is, that when an artery is deprived of its sheath for an extent greater than its distance of retraction, the hemorrhage is mortal. I have not yet had time to look over the original paper; but it appears to me, that it would be desirable to know precisely to what sized arteries the author is referring, when he is making some of the above inferences. The size and condition of each animal, the subject of experiment, should also be particularly specified; as experiments made on the femoral artery of a lady's lapdog would surely not have the same results as those performed on the same artery of a large terrier, setter, or Newfoundland dog.

According to Dr. Jones, the lymph which fills up the wound of an artery is poured out very freely both from the vessel and the surrounding parts, and it accumulates around the artery, particularly over the wound, where it forms a more distinct tumour. The exposed surrounding parts at the same time inflame, and pour out coagulating lymph, with which the whole surface of the wound becomes covered, and which completely excludes the artery from the external wound. This lymph granulates, and the wound is filled up and healed in the usual manner.—(See *Jones on Hemorrhage, p.* 113, *&c.*)

SURGICAL MEANS OF SUPPRESSING HEMORRHAGE.

It must be plain to every one who understands the course of the circulation, that pressure, made on that portion of a wounded artery which adjoins the wound towards the heart, must check the effusion of blood. The current of blood in the veins, running in the opposite direction, requires the pressure to be applied to that side of the wound which is most remote from the heart. However, on account of the freedom and facility with which the blood is transmitted through the anastomoses, from the portion of the artery above the point of pressure into the lower continuation of the artery, such pressure will often only check, and not effectually stop the bleeding, unless the part of the vessel directly below the wound be also compressed or secured. As pressure is the most rational means of impeding hemorrhage, so it is the most effectual; and almost all the plans employed for this purpose, are only modifications of it. The tourniquet, the ligature, the application of a roller and compresses, even agaric itself, only become useful in the suppression of hemorrhage, on the principle of pressure: the cautery, caustics, and stypics, however, have a different mode of operation

In order to prevent a wounded person from dying of hemorrhage, Celsus advised the wound to be filled with dry lint, over which was laid a sponge dipped in cold water, and pressed on the part with the hand If, not

withstanding these means, the hemorrhage should continue, he recommends repeatedly applying fresh lint, wet with vinegar; but he is against the use of corroding escharotic applications, on account of the inflammation which they produce; or only sanctions the employment of the mildest ones. When the hemorrhage resists these methods, *he advises two ligatures to be applied to the wounded part of the vessel, and then dividing the portion situated between them:* "*Quod si illa quoque profluvio vincuntur, venæ, quæ sanguinem fundunt, apprehendendæ, circaque id, quod ictum est, duobus locis deligandæ, intercidendæque sunt, ut et in se ipsæ coeant, et nihilominus ora præclusa habeant.*" —(*Lib.* 5, *cap.* 26.) When the ligature was impracticable, the wound bled dangerously, and no large nerves nor muscles were situated in the bleeding part Celsus proposed the actual cautery.

Galen also mentions tying the vessels for the purpose of stopping hemorrhage; and there are some traces of the same information in other authors, who lived before him, as Archigenes and Rufus. Probably, however, the ligature was little used at these early periods, as may be inferred from the multitude of astringents, caustics, and other applications, which were advised for stopping bleeding, and in which less confidence would have been put, had the use of the ligature been familiarly known. No one can doubt, that if the old surgeons had had many opportunities of seeing the advantages of the ligature, they would soon have used it after amputations; but so far were they from adopting such practice, that Albucasis, a long while afterward, refused to amputate at the wrist, lest he should see his patient bleed to death.

Paré is considered as the first who regularly employed the ligature after amputation. His method having been attacked, he modestly defends it in the part of his works entitled *Apologie*, where he takes great care to impute the origin of it to the ancients, and cites many of them who have made mention of it. However, he thinks its utility in amputations of such consequence, that he ascribes his first adoption of this practice to inspiration of the Deity.

The method in which the ancients placed most confidence for stopping hemorrhage after the amputation of a limb, was the cauterization of the cut vessel, and surrounding flesh. The parts thus affected by the heat formed an eschar, of greater or less thickness, which blocked up the opening of the vessel, and hindered the blood from escaping. The separation of the eschar, however, which frequently took place too soon, occasioned a return of hemorrhage, and rendered it the more dangerous, as its suppression was now more difficult than before the cautery had been applied. Sometimes the instrument, being too much heated, immediately brought away with it the eschar. At the present time, the cautery is never employed as a means of suppressing hemorrhage, or, at most, only in a few very unusual cases, in which neither compression nor the ligature can be made use of. In Great Britain, the cautery may be said to be entirely exploded; but in France, the best hospital surgeons now and then employ it to stop bleedings from the antrum and the mouth.

The old surgeons also very commonly applied to bleeding parts pledgets, dipped in boiling turpentine—a practice that has long been most justly abandoned.

ASTRINGENTS, STYPTICS, &c.

Le Dran, in his Treatise on the Operations of Surgery, says that a button of vitriol, or alum, applied and properly confined on the extremity of the vessel, is sufficient to stop the hemorrhage in amputations. Heister recommends the application of vitriol, in preference to the ligature, in the amputation of the forearm. Great praises have also been conferred on agaric, and sponge, for their styptic properties. Solutions of iron, and all the mineral acids in various forms, have been recommended to the public, as remedies of the same kind, and possessing great efficacy. The ancients, centuries ago, left no application of this nature untried, and the pretended discoveries of new and more effectual styptics in later times may almost all be met with in their writings. This fact merits particular notice, because the little success attending their practice, especially when bleeding from a considerable artery was to be suppressed, clearly proves what little reliance ought to be placed on means of this description.—(*Encyclopédie Méthodique, partie Chir.*) The most which styptics can do is to stop hemorrhages from small arteries; but they ought never to be trusted when large vessels are concerned.

There is no doubt, that cold air has a styptic property: by which expression I mean, that it promotes the contraction of the vessels; for no styptics can contribute to make the blood coagulate, though such an erroneous idea is not uncommon. We frequently tie, on the surface of a wound, every artery that betrays the least disposition to bleed, as long as the wound continues exposed to the air. We bring the opposite sides of this wound into contact, and put the patient to bed. Not an hour elapses before the renewal of hemorrhage compels us to remove the dressings. The wound is again exposed to the air, and again the bleeding ceases. This often happens in the scrotum, after the removal of a testicle, and on the chest, after the removal of a breast. The proper conduct in such cases, is not to open the wound unnecessarily, but to apply pressure, or else wet linen to the part, so as to produce such an evaporation from its surface, as shall create a sufficient degree of cold to stop the bleeding. As all styptics are more or less irritating, no judicious practitioners apply them to recent wounds. However, for the suppression of hemorrhage from diseased surfaces, where the vessels seem to have lost their natural disposition to contract, these applications are sometimes indicated.

COMPRESSION.

We have already remarked that all the best means of checking hemorrhage operate on the principle of pressure; the actual and potential cautery, and some styptics excepted: the first two of which operate by forming a slough, which stops up the mouths of the vessels; while the latter operate by promoting their contraction. Let us next consider the various modifications of pressure.

In a dissertation on the manner of stopping hemorrhage, printed in the *Mém. de l'Acad. des Sciences, année* 1731, Petit endeavoured to prove, that different articles, praised as infallible specifics, would seldom or never have succeeded without compression. Even when caustics were employed, it was usual to bind compresses tightly on the part, so as to resist the impulse of the blood in the artery, and the premature separation of the eschar. Had this precaution not been taken, Petit believes hemorrhage would almost invariably have followed, and indeed, notwithstanding the pains taken to avert it by suitable compression, it did too frequently take place on the detachment of the eschar. Petit has noticed that the end of a finger, gently compressing the mouth of a vessel, is a sufficient means of stopping hemorrhage from it, and that nothing else would be necessary, if the finger and stump could always be kept in this posture. Hence he endeavoured to obviate these difficulties by inventing a machine which securely and incessantly executed the office of the finger. The instrument was a double tourniquet, which, when applied, compressed at once both the extremity of the divided artery and its trunk above the wound. The compression on the end of the vessel was permanent; that on the trunk was made only at the time of dressing the wound, or when it was necessary to relax the other. An engraving and particular description of the instrument are to be found in Petit's memoir.

Surgeons formerly filled the cavities of wounds with lint or charpie, and then made pressure on the bleeding vessels, by applying compresses and a tight roller over the part. The practitioners of the present day are too well acquainted with the advantages of not allowing any extraneous substance to intervene between the opposite surfaces of a recent wound, to persist in the above plan. They know that the sides of the wound may be brought into contact, and that compression may yet be adopted, so as both to restrain particular hemorrhages, and rather promote than retard the union of the wound.

When the blood does not issue from any particular vessels, but from numerous small ones, compression is preferable to the ligature. In the employment of the latter, it would be necessary to tie the whole surface of the wound. The sides of the wound are to be brought accurately together, and compresses are then to be placed over the part, and a roller to be applied with sufficient tightness to make effectual pressure, but not so forcibly as to produce any chance of the circulation in the limb being completely stopped

If, in bleeding from large arteries, compression can ever be prudently tried, it is when these vessels lie immediately over a bone. Bleedings from the radial and temporal arteries are generally cited as cases of this kind, though from the many instances of failure which I have seen happen where the first of these vessels is concerned, I should be reluctant either to advise or make such an attempt. Compression is sometimes tried, when the brachial artery is wounded in phlebotomy. Here it is occasionally tried, in preference to the ligature, because the latter cannot be employed without an operation to expose the artery.

When there is a small wound in a large artery, the following plan may be tried: a tourniquet is to be applied, so as to command the flow of blood into the vessel. The edges of the external wound are next to be brought into contact. Then a compress, shaped like a blunt cone, and which is best formed of a series of compresses, gradually increasing in size, is to be placed with its apex exactly on the situation of the wound in the artery. This *graduated compress*, as it is termed, is then to be bound on the part with a roller.

In this manner, I once healed a wound of the superficial palmar arch, in a young lady in Great Pulteney-street. The outward wound was very small, and though the hemorrhage was profuse, I conceived that it might be permanently stopped, if compression could be so made as to keep the external wound incessantly and firmly covered for the space of a day or two. At first, I tried a compress of lint, bound on the part with a roller; but this proving ineffectual, I took some pieces of money, from the size of a farthing to that of a half-crown, and, wrapping them up in linen, put the smallest one accurately over the wound, so as completely to cover it. Then the others were arranged, and all of them were firmly confined with a roller, and the arm kept as quiet as possible in a sling. They were taken off after three days, and no hemorrhage ensued.

It is to be observed, that the palmar fascia, in this instance, would prevent the compression from operating on the vessel; but the case shows that this artery, when wounded, is capable of healing, if the blood be completely prevented from getting out of the external wound by the proper application of compression. Were the outer wound too large to admit of this plan, it would probably be the safest practice to cut down, at once, to the ulnar artery, and put a ligature round it, though, as this would only certainly stop the bleeding from one end of the vessel in the hand, pressure on the wound would yet be necessary. I have never seen a surgeon succeed in taking up the artery in the hand.

Besides compressing the wounded part of the artery, some surgeons also apply a longitudinal compress over the track of the vessel above the wound, with a view of weakening the flow of blood into it. Whatever good effect it may have in this way, is more than counterbalanced by the difficulty which it must create to the circulation in the arm. If the graduated compress be properly arranged, an effusion of blood cannot possibly happen, and pressure along the course of the artery must at all events be unnecessary. After relaxing the tourniquet, if no blood escape from the artery, the surgeon (supposing it to be the brachial artery wounded) should feel the pulse at the wrist, in order to ascertain that the compression employed is not so powerful as entirely to impede the circulation in the forearm and hand. The arm is to be kept quietly in a sling, and, in forty-eight hours, if no bleeding take place, there will be great reason to expect that the case will do well. In another work, I have given an engraving and description of an instrument invented by Plenck, for making pressure on the wounded brachial artery, at the bend of the arm, without pressing upon the whole circumference of the limb and consequently without stopping the circulation. No one, however, would prefer compression when large arteries are injured, except in the kind of cases to which we have just now adverted, or in those in which the wounded vessel can be firmly compressed against a subjacent bone. Sometimes the compresses slip off, or the bandages become slack, and a fatal hemorrhage may arise; and a still greater risk is that of mortification from the constricted state of the limb. When the method is tried, the tourniquet should always be left loosely round the limb, ready to be tightened in an instant. Sometimes the external wound heals, while the opening in the artery remains unclosed, and a false aneurism is the consequence.

TOURNIQUET.

When hemorrhage takes place from a large artery in one of the limbs, where the vessel can be conveniently compressed above the wound in it, a tourniquet, judiciously applied, never fails to put an immediate stop to the bleeding.

Before the invention of this instrument, which did not take place till the latter part of the 17th century, surgery was really a very defective art. No important operation could be undertaken on the extremities, without placing the patient in the most imminent peril; and many wounds were mortal, which, with the aid of this simple contrivance, would not have been attended with the least danger.

The first invention of the tourniquet has been claimed by different surgeons, and even different nations. But, whoever was the inventor, it was first presented to the public in a form exceedingly simple; so much so, indeed, that it seems extraordinary that its invention did not happen sooner. A small pad being placed on the principal artery of a limb, a band was applied over it, so as to encircle the limb twice. Then a stick was introduced between the two circles of the band, which was twisted: thus the pad was made completely to stop the flow of blood into the lower part of the vessel.

Although in the *Armamentarium Chirurgicum* of Scultetus there is a plate of a machine invented by this author for compressing the radial artery by means of a screw, J. L. Petit is universally allowed to be the first who brought the tourniquet to perfection, by combining the circular band with a screw, so that the greatest pressure may operate on the principal artery.

The advantages of the modern tourniquet are, that its pressure can be regulated with the utmost exactness; that it operates chiefly on the point where the pad is placed, and where the main artery lies; that it does not require the aid of an assistant to keep it tense; that it completely commands the flow of blood into a limb; that it can be relaxed or tightened in a moment; and that, when there is reason to fear a sudden renewal of hemorrhage, it can be left slackly round the limb, and, in case of need, tightened in an instant. Its utility, however, is confined to the limbs, and as the pressure necessary to stop the flow of blood through the principal artery completely prevents the return of blood through the veins, its application cannot be made very long without inducing mortification. It is only of use also in putting a sudden stop to profuse hemorrhages for a time, that is, until the surgeon has put in practice some means, the effect of which is more permanent.

LIGATURE.

The ancients were quite unacquainted with the use of the tourniquet, and though some of their writers have made mention of the ligature, they do not seem to have known how to make proper use of it, nor to have possessed any other certain means of suppressing hemorrhage from wounds. In modern times, it is easily comprehensible, that when any great operation was undertaken, while surgery was so imperfect, there was more likelihood of the patient's life being shortened than lengthened, by what was attempted. Under these circumstances, it is not surprising that the old practitioners should have taken immense pains to invent a great many topical astringents. But now that the ligature is known to be a means which is safer and less painful than former methods, no longer search need be made for specifics against hemorrhage.

It may, indeed, be set down as a rule in surgery, that whenever large arteries are wounded, no styptic application should ever be employed, but immediate recourse had to the ligature, as being, when properly applied, the most simple and safe of all methods.

In order to qualify the reader to judge of the best mode of applying ligatures to arteries, I shall first explain to him their effect on these vessels, as related by Dr. Jones.

This gentleman learned from Dr. J. Thomson, of Edinburgh, that in every instance in which a ligature is applied around an artery, without including the surrounding parts, the internal coat of the vessel is torn through by it; and that this fact had been originally

noticed by Desault. Dr. Thomson even demonstrated to Dr. Jones, on a portion of artery taken from the human subject, that the internal and middle coats are divided by the ligature.—(*Jones, p.* 126.)

This led Dr. Jones to make some experiments on the arteries of dogs and horses, tending to the conclusion, that *when several ligatures are applied round an artery* with sufficient tightness to cut through its internal and middle coats, although the cords be immediately afterward removed, the vessel will always become impervious at the part which was tied, as far as the first collateral branches above and below the obstructed part. Dr. Jones thinks it reasonable to expect that the obstruction produced in the arteries of dogs and horses, in the manner he has related, "might be effected by the same treatment in the arteries of the human subject; and, if it should prove successful, it might be employed in some of the most important cases in surgery. The success of the late important improvements which have been introduced in the operation for aneurism, may perhaps appear to most surgeons to have rendered that operation sufficiently simple and safe; but if it be possible to produce obstruction in the canal of an artery of the human subject in the abovementioned manner, may it not be advantageously employed in the cure of aneurism; inasmuch as nothing need be done to prevent the immediate union of the external wound?" Dr. Jones next questions whether this mode of obstructing the passage of blood through the arteries may not also be advantageously practised in cases of bronchocele?—(*P.* 136.)

Subsequent experimenters have not been equally successful with Dr. Jones in obtaining the obliteration of the cavity of the vessel after this operation. Did this difference depend upon their having tied the vessel only in one place? Mr. Hodgson tried the experiment in two instances upon the carotid arteries of dogs; and in neither of them was the cavity of the vessel obliterated. The same experiment has been repeated by several surgeons upon the arteries of dogs and horses; but in no example, as far as Mr. Hodgson knows, has the complete obliteration of the cavity of the vessel been accomplished. However, as an effusion of lymph is an invariable consequence of the operation, the want of union is owing to the opposite sides of the vessel not being retained in a state of contact, so as to allow of their adhesion.—(See *Observations on the Application of the Ligature to Arteries, &c. by B. Travers, vol.* 4, *Med. Chir. Trans.*) The presence of the ligature, in the common mode of its application, effects this object; and for the success of Dr. Jones's experiment, it appeared only necessary that the opposite sides of the wounded vessel should be retained in contact until their adhesion is sufficiently accomplished to resist the passage of the blood through the tube. This object might probably be effected by compression; but the inconveniences attending such a degree of pressure as shall retain the opposite sides of an artery in contact at the bottom of a recent wound, are too great to permit its employment. It occurred to Mr. Travers, that if a ligature were applied to an artery, and suffered to remain only a few hours, the adhesion of the wounded surfaces would be sufficiently accomplished to ensure the obliteration of the canal; and by the removal of the ligature at this period, the inconveniences attending its stay would be obviated. The danger produced by the continuance of a ligature upon an artery arises from the irritation which, as a foreign body, it produces in its coats. Ulceration has never been observed to commence in less than twenty-four hours after the application of a ligature; while it is an ascertained fact that lymph is in a favourable state for organization in less than six hours, in a wound the sides of which are preserved in contact.—(*Jones, chap.* 4, *exp.* 1.) If it be sufficient, therefore, to ensure their adhesion, that the wounded coats of an artery be kept in contact by a ligature only three or four hours, ulceration and sloughing may in a great degree be obviated by promoting the immediate adhesion of the wound. Justified by this reasoning, Mr. Travers performed several experiments, by which he ascertained, that if a ligature be kept six, two hours, or even one hour upon the carotid artery of a horse, and then removed, the adhesion is sufficiently advanced to secure the permanent obliteration of the canal. It appeared probable that the same result would be obtained upon the healthy artery of a human subject.—(*Hodgson on the Diseases of Arteries, &c. p.* 228, *et seq.*) Mr. A. C. Hutchison, in the year 1800, tied the brachial arteries of two dogs, and removed the ligatures immediately after their application. In both instances, the complete obliteration of the canal of the artery was the consequence of the operation.—(See *Practical Observations in Surgery, p.* 103.) He has also tried this method, as modified by Mr. Travers, in an operation which he performed for a popliteal aneurism in a sailor, in Nov. 1813. A double ligature was passed under the femoral artery. The ligatures were tied with loops or slip-knots, about a quarter of an inch of the vessel being left undivided between them. All that now remained of the pulsation in the tumour was a slight undulatory motion. Nearly six hours having elapsed from the application of the ligatures, the wound was carefully opened, and the ligatures untied and removed, without the slightest disturbance of the vessel. In less than half a minute afterward the artery became distended with blood, and the pulsations in the tumour were as strong as they had been before the operation. Mr. Hutchison then applied two fresh ligatures; hemorrhage afterward came on; amputation was performed, and the patient died.—(See *Practical Observations in Surgery, p.* 102, *&c.*) Now, as Mr. Hutchison chose to apply other ligatures, on finding that the pulsation returned, the above case only proves that the artery was not obliterated in about six hours, and we are left in the dark respecting the grand question, namely, whether the vessel would have become obliterated by the effusion of coagulating lymph and the adhesive inflammation, notwithstanding the return of circulation through it. As for the hemorrhage which occurred, I think it might have been expected, considering the disturbance and irritation which the artery must have sustained in the proceedings absolutely necessary for the application of not less than four ligatures, and the removal of two of them. According to my ideas, only one ligature ought to have been used, and none of the artery detached. We also have no description of the sort of ligatures which were employed; an essential piece of information in forming a judgment of the merits of the preceding method. The application, removal, and reapplication of ligatures are not consistent with the wise principles inculcated by the late Dr. Jones, and have, in more instances than that recorded by my friend Mr. Hutchison, brought on ulceration of the artery and hemorrhage. For farther information on the question concerning the propriety of withdrawing the ligature previously to its detachment, see the article *Aneurism.*

From Dr. Jones's experiments, it appears that the first effects of a ligature upon an artery are, a complete division of its internal and middle coats, the bringing of its wounded surfaces into contact with each other, and an obstruction to the circulation of the blood through its canal. There must be a small quantity of stagnant blood just within the extremity of the artery but this does not, in every instance, immediately form a coagulum capable of filling up the canal of the artery. In most cases, only a slender coagulum is formed at first, which gradually becomes larger by successive coagulations of the blood; and hence the coagulum is always at first of a tapering form, with its base at the extremity of the artery. But, as Dr. Jones remarks, the formation of this coagulum is not material; for soon after the ligature has been applied, the end of the artery inflames, and the wounded internal surface of its canal being kept in close contact by the ligature, adheres and converts this portion of the artery into an impervious and, at first, slightly conical sac. It is to the effused lymph that the base of the coagulum adheres, when found to be adherent. Lymph is also effused between the coats of the artery, and among the parts surrounding its extremity. In a little time, the ligature makes the part on which it is directly applied ulcerate, and, acting as a tent, a small aperture is formed in the layer of lymph effused over the artery. Through this aperture a small quantity of pus is discharged, as long as the ligature remains; and finally, the ligature itself also escapes, and the little cavity which it has occasioned granulates and fills up, and the external wound heals, leaving the cellular substance a little beyond the end of the artery much thickened and indurated.—(*Jones, p.* 159. 161.)

In short, when an artery is properly tied, the following are the effects, as enumerated by Dr. Jones:

1. To cut through the internal and middle coats of the artery, and to bring the wounded surfaces into perfect apposition.

2. To occasion a determination of blood to the collateral branches.

3. To allow the formation of a coagulum of blood just within the artery, provided a collateral branch be not very near the ligature. It merits particular notice, however, that though the nearness of a collateral branch prevents the formation of the coagulum, it cannot always prevent the completion of the adhesive process. In the experiments made on the arteries of horses and dogs by Mr. Travers, the ligature was purposely applied close to large collateral branches, yet the vessels were safely obliterated.—(See *Med. Chir. Trans. vol.* 6, *p.* 658. 660.)

4. To excite inflammation in the internal and middle coats of the artery, by having cut them through, and, consequently, to give rise to an effusion of lymph, by which the wounded surfaces are united, and the canal is rendered impervious; to produce a simultaneous inflammation on the corresponding external surface of the artery, by which it becomes very much thickened with effused lymph; and, at the same time, from the exposure and inevitable wounding of the surrounding parts, to occasion inflammation in them, and an effusion of lymph, which covers the artery, and forms the surface of the wound.

5. To produce ulceration in the part of the artery around which the ligature is immediately applied, viz. its external coat.

6. To produce indirectly a complete obliteration, not only of the canal of the artery, but even of the artery itself, to the collateral branches on both sides of the part which has been tied.

7. To give rise to an enlargement of the collateral branches.—(*Jones*, *p.* 163, 164.)

Every part of an artery is organized in a similar manner to the other soft parts, and its coats are susceptible of the same process of adhesion, ulceration, &c. as the other parts are. Hence, the precautions taken to secure the adhesion of other parts should be observed for the same purpose with regard to an artery. The vessel is put in a state to admit of adhesion by the ligature, which, when properly applied, cuts through its internal and middle coats, keeps their cut surfaces in contact, and affords them an opportunity of uniting by the adhesive inflammation, as other cut surfaces do. The immediate stoppage of the bleeding is merely the incipient and temporary part of what the ligature has to accomplish; it has also to effect the adhesion of the internal and middle coats of the artery, which, being the thing on which the permanent suppression of hemorrhage depends, is the most important. The size and form of the ligature, whether completely flat or irregular, have not been, as Dr. Jones remarks, sufficiently attended to; nor is the degree of force employed in tying the artery often considered. Some surgeons, wishing to guard against the ligature slipping off, tie it with very considerable force; while others, apprehensive of cutting through the artery, or of occasioning too early a separation of the ligature, draw it only sufficiently tight just to prevent the escape of blood. A broad, flat ligature is not likely to make such a wound in the internal and middle coats of the artery as is most favourable to adhesion, because it is scarcely possible to tie it smoothly round the vessel, which is very likely to be thrown into folds or puckered by it, and consequently to have an irregular bruised wound made in its middle and internal coats. By covering also a considerable space of the external coat, it may destroy the very vessels which pass on it in their way to the cut surfaces of the inner coats, and thus render them incapable of inflaming. Even supposing the wound to unite, still such a ligature may cover that part of the external coat which is directly over the newly united part, and, consequently, as soon as it has produced ulceration through the external coat, it will cause the same effect on the newly united parts, and, of course, secondary hemorrhage.—(*Jones*, *p.* 168.)

When a ligature is of an irregular form, it is apt to cut through the internal and middle coats of an artery more completely at some parts than others; but these coats must be perfectly cut through, in order to produce an effusion of lymph from the inside of the vessel, which seems to adhere most securely at its cut surfaces.

Also, when the ligature is not applied with sufficient tightness, the inner coats of the artery will not be properly cut through. Dr. Jones thinks that the ligature, being sometimes put on so as to deviate from a circle, has a tendency to produce secondary hemorrhage.

Dr. Jones conceives that ligatures are best when they are round and very firm; and he adds, that though only a slight force is necessary to cut through the internal and middle coats of an artery, it is better to tie the vessel more tightly than is necessary merely to cut through its inner coats, because the cut surfaces will thus be more certainly kept in contact; the separation of the ligature expedited; and the danger of ulceration spreading to the newly cicatrized part diminished. The external part will never ulcerate through before the inner ones have adhered. The limb, however, should be kept in a perfectly quiet state.

I am sincerely glad to find that so accurate an observer as Dr. Jones has refuted the idea that ligatures occasionally slip off the vessels, in consequence of the violent impulse of the blood. In fact, the blood does not continue to be impelled against the extremity of the artery, with the same impetuosity with which it circulated through the vessel before it was tied. The blood is immediately determined into the collateral branches, nor is there any pulsation for some way above the ligature.

Dr. Jones much more rationally imputes this occasional accident either to the clumsiness of the ligature, which prevents its lying compactly and securely round the artery, or to its not having been applied with sufficient tightness; or to its having that very insecure hold of the vessel which the deviation from the circular application must occasion.—(*P.* 173.)

Dr. Jones is of opinion, that in cases of aneurism, in which the artery has only been tied with one ligature, and left undivided, and in which secondary hemorrhage has arisen, that this has most probably been owing either to a diseased state of the artery; to various contrivances for compressing a large portion of the vessel; to having a loose ligature above the one which is tied; or, lastly, to not tying the artery sufficiently tight to cut through the internal and middle coats, so as to fit them for adhesion. The latter fault can hardly fail to produce a gradual ulceration of those coats, and of course bring on hemorrhage, which returns with greater violence as the ulceration advances.—(*P.* 176.)

These reflections must also obviously explain why Scarpa's practice of using a largish ligature, with the intervention of a piece of cloth between the cord and the vessel, for the express purpose of hindering the inner coats of the vessel from being divided, must be objectionable, because it may be set down as an axiom in all operations where large arteries are to be tied, that the quantity of extraneous substances in the wound, and particularly of such as are in contact with the artery, should be diminished as much as possible. And though I may be disposed to go so far with Scarpa as to believe that the interposition of a piece of cork or wood is worse than that of a cylinder of linen, I cannot accede to the proposition that the latter is free from objection, because it rather acts as a cushion than as a body likely to bruise.—(See *Mem. on the Ligature of Arteries*, *p.* 44.)

With the differences in the constitutions of man and animals, I know that the results of experiments on the latter can never be looked upon as a positive proof of what would happen from the same experiments performed on the human subject. The stronger or weaker impulse of the heart, the more or less coagulable nature of the blood, the greater or less degree of general and local irritability, the more or less quick tendency to adhesive inflammation and ulceration, are circumstances which must make in different animals the same experiments lead to opposite results. The question whether a small round ligature, or a larger flat one, with a piece of linen between it and the vessel, be best, must therefore, after all, be decided, not by Dr. Jones's experiments, nor those of Scarpa, or Misiel, but by the practice of surgery on the human body; and that the principles defended in this Dictionary are on the whole to be preferred, can hardly be questioned by any man who knows how much less frequent secondary hemorrhage now is in this metropolis than it was formerly, when those principles were neither observed nor comprehended.—(See *Amputation*, *Aneurism*, *Arteries*, and *Ligature*.)

Dr. Jones seems to consider, that the advantage of the retraction of the *divided* artery within the cellular membrane is compensated, in the case of the *undivided* artery, by the speedy and profuse effusion of lymph, which takes place over and round the vessel at the tied part, and even covers the ligature itself. Another cause of secondary hemorrhage is, the including of other parts in the ligature, together with the artery; by doing which the division of the inner coats of the vessel may be prevented.

In the valuable publication of Dr. Jones to which I have so freely adverted, some secondary hemorrhages are also imputed to the hidden separation or laceration of the recently united parts of an artery, by premature and extraordinary exertions of the patient. Hence, he strongly insists on keeping a limb in which a large artery has been tied perfectly at rest.

I shall conclude these remarks on the ligature with a few practical rules.

1. Always tie a large artery as separately as possible, but still let the ligature be applied to a part of the vessel which is close to its natural connexions.

Besides the reasons for this practice already specified, we may observe, that including other substances in the ligature causes immense pain, and a larger part of a wound to remain disunited. The ligature is also apt to become loose, as soon as the substance between it and the artery sloughs or ulcerates. Sometimes the ligature, thus applied, forms a circular furrow in the flesh, and remains a tedious time incapable of a separation.

The blood-vessels being organized like other living parts, the healing of a wounded artery can only take place favourably when that part of the vessel which is immediately contiguous to the ligature continues to receive a due supply of blood through its vasa vasorum, which are ramifications of the collateral arteries. Hence the disadvantage of putting a ligature round the middle of a portion of an artery, which has been separated from its surrounding connexions; and hence the utility of making the knot as closely as possible to that part of the vessel which lies undisturbed among the surrounding flesh.

Small arteries neither allow nor require these minute attentions to the mode of tying them.

2. When a divided artery is large, open-mouthed, and quite visible, it is best to take hold of it, and raise its extremity a little way above the surface of the wound with a pair of forceps. When the vessel is smaller, the tenaculum is the most convenient instrument.

3. While the surgeon holds the vessel in this way, the assistant is to place the noose of the ligature round it, and tie it according to the above directions. In order that the noose may not rise too high, and even above the mouth of the artery, when it is tightened, the ends of the ligature must be drawn as horizontally as possible, which is best done with the thumbs. A knot is next to be made.

4. As ligatures always operate in wounds as extraneous bodies, and one-half of each is sufficient for the removal of the noose when detached, the other should be cut off close to the knot, and taken away.

As we have explained in the article *Amputation*, and as we shall notice again in speaking of the *Ligature*, trials have of late years been made of the practice of cutting off both ends of the ligature close to the knot, with a view of diminishing, as far as possible, the quantity of extraneous substances in the wound. This plan requires the use of very small silk ligatures, in order to be duly judged of.—(See *Mr. Lawrence's Obs. in Medico-Chir. Trans. vol.* 6, *p.* 156, *et seq.*)

5. When a large artery is completely divided, two ligatures, one to the upper, the other to the lower part of the vessel are commonly necessary, in consequence of the anastomosing branches conveying the blood very readily into the part of the artery most remote from the heart, as soon as the first ligature has been applied.

6. When a large artery is only punctured, and compression cannot be judiciously tried, the vessel must be first exposed by an incision, and then a double ligature introduced under it, with the aid of an eye-probe. One ligature is to be tied above, the other below the bleeding orifice; with due attention to the principles explained in this article, and that on *Aneurism*.

7. Ligatures usually come away from the largest artery ever tied in about a fortnight, and from those of moderate size in six or seven days. When they continue attached much beyond the usual period, it is proper to draw them very gently every time the wound is dressed, for the purpose of accelerating their detachment. Great care, however, is requisite in doing this; for, as Dr. Jones remarks, as long as the ligature seems firmly attached, pulling it rather strongly must act more or less on the recently cicatrized extremity of the artery, which is not only contiguous to it, but is still united to that portion of the artery (the external coat) which detains the ligature.—(*Jones*, *p.* 162.)

In particular individuals there appears to be an extraordinary tendency to profuse hemorrhage from very slight injuries. An instance of this kind has been recorded by Mr. Blagden, where a fatal hemorrhage arose from the extraction of a tooth. The patient, who was twenty-seven years of age, had had a tooth extracted when a boy, in consequence of which operation the bleeding continued for twenty-one days from the socket before it ceased. A very slight cut on the head was also followed by an alarming bleeding, which could not be stopped by pressure, styptics, or the ligature, so that it became necessary to apply the kali purum, which succeeded. On his having another carious tooth taken out, a profuse bleeding followed, which resisted the effect of styptics, caustic, and every means adopted to stop up the socket. The actual cautery was tried in vain. The dangerous condition of the patient seemed to leave no other resource, but that of tying the carotid artery, which was done by Mr. Brodie. But even this proceeding failed to suppress the hemorrhage, which proved fatal.—(See *Med. Chir. Trans. vol.* 8, *p.* 224, *Lond.* 1817.) On the mode of stopping hemorrhage from the sockets of the teeth, the reader may find some remarks in the *Edin. Med. and Surg. Journ. No.* 58, *p.* 157.

The hemorrhage from the bites of leeches sometimes proves exceedingly obstinate, and instances of death from this cause have occasionally happened, particularly in children. When common methods fail, the plan has been recently tried of passing a fine sewing needle through the skin on one side of the wound, and then another through the skin on the opposite side, and then twisting some thread round the needles, so as to draw them together, and close the bite. The experiment fully answered.—(See *Lond. Med. Repository*, *Jan.* 1819, *p.* 23—26.)

Repository, vol.* 7, *p.* 353. *The author relates several experiments for the purpose of ascertaining the utility of tying arteries with such ligatures, and cutting the two ends off close to the knot. They were performed on the carotids of dogs and asses. The conclusions are unfavourable to the practice. After one case of amputation, where the method was tried, the stump healed slowly, and for several months small abscesses repeatedly formed.*

HEMORRHOIDS. (From *αἷμα*, blood, and *ῥέω*, to flow.) *Piles*, divided into such as do not bleed, and termed *blind*, and into others subject to occasional hemorrhage, and distinguished by the epithet *open*. The etymological meaning of the word is evidently only a discharge of blood. Surgeons, however, sanctioned by long custom, have generally implied by the term *hemorrhoids* either a simple bleeding from the veins of the lower part of the rectum, recurring more or less frequently, yet not accompanied with any distinguishable permanent tumours within, or on the outside of the anus; or else swellings formed by a varicose distention and morbid thickening of those vessels, either with or without occasional hemorrhage; or lastly, tumours originally produced by effused blood, but subsequently converted into an organized substance.—(*Abernethy, Surgical Works, vol.* 2, *p.* 234.)

According to Richter, blind hemorrhoids consist of preternatural cysts or sacs at the lower extremity of the rectum, from the size of a pea to that of an apple. Sometimes they are distended with blood, and very much swelled; and at other periods entirely subside; though, when they have been often considerably swelled, they never quite disappear, but are alternately in a full enlarged state and empty and flaccid. Indeed, the more frequent and considerable the enlargement has been, the greater is their size. It is generally supposed, that these tumours or cysts are varicose expansions of the veins of the rectum; and probably, says Richter, this may sometimes really be the case; but the disease is not always of this nature. In particular instances, and, perhaps, in most cases, they arise from an extravasation of blood under the inner coat of the rectum; and then the cyst is altogether formed by this membrane, and not by the vein. The following circumstances furnish proof of what has been here observed. Hemorrhoids are sometimes as large as a walnut or apple; yet it is scarcely credible, that a mere varix could attain such a size. When cut away, the bleeding is often very slight, even when they are large. Surely, if the tumours were varices, there would always be profuse hemorrhage. Sometimes the cyst is found quite empty; but how can a varix be supposed to be in this state? The shape of hemorrhoids is also remarked to be subject to greater variety than can hardly attend dilatations of veins: thus they are sometimes oblong, sometimes cylindrical, like a finger, &c. Lastly, when cut away, the sac is plainly seen to consist only of a single membrane.—(*Anfangsgr. der Wundarzn. b.* 6, *p.* 395, *ed.* 2, *Gött.* 1802.)

At the same time, it should be recollected that "the blood sometimes coagulates in the dilated vein, and the swelling becomes hard, inflamed, and very painful. The coagulum is subsequently absorbed, but the thickened coats of the vein and the surrounding parts form a tumour which is liable to inflame and afford great distress."—(*Hodgson on Diseases of Arteries, &c. p.* 566.) In short, all surgeons who consider the disease as varices, admit, with Sir E. Home, that in cases of long standing, the contents of hemorrhoidal tumours "coagulate and become solid; their coats increase in thickness, and they resemble pendulous excrescent tumours in other situations in the body.—(*On Ulcers, &c.*) Availing himself of the extensive opportunity afforded by his dissecting-room, Mr. Kirby has taken some pains to ascertain the nature of these tumours; and he observes, "I cannot say, that they seemed to be formed of a varicose distention of the great hemorrhoidal vein, even in a single instance. In every case of external hemorrhoids, the tumour appeared to be composed of a prolongation of the cellular substance in a state of unusual firmness, surrounded by some veins, and covered by the integuments. The veins were branches of the internal iliac. In every case of internal hemorrhoid, the structure was pretty similar: the veins, however, seemed enlarged, and were branches of the hemorrhoidal."—(*On certain severe Forms of Hemorrhoidal Excrescence, p.* 40.)

The opinion that piles are formed of cells filled with blood is also adopted by Dr. Ribes. The distention of the hemorrhoidal veins with blood, he observes, gives rise to varices; but if any of their blood is extravasated in the cellular membrane, at the inferior and internal part of the anus, hemorrhoids are the result. If the inferior mesenteric vein be dissected in hemorrhoidal patients, the ramifications of the vessel are seen terminating in these cysts of blood, and on completely removing the whole, the hemorrhoids appear suspended from the branches of the vein, as grapes from the vine.—(See *Révue Méd. t.* 1, 8vo. 1820.) Montegre, well known as the author of a copious treatise on the present subject, is the only writer who defines a hemorrhoid to be a preternatural determination of blood (*fluxion sanguine*) to the extremity of the rectum, because he conceives that hemorrhage, swelling, &c. are accidental circumstances, not constantly attending the disease.—(See *Dict. des Sciences Méd t.* 20, *p.* 445.)

Whether the account of some piles being formed of distinct cysts or sacs of blood be correct or not, there is no doubt, that the tumours sometimes consist of a varicose enlargement of the branches of the hemorrhoidal veins. Were this not the fact, how could cases like the following ever take place? "One of my patients (says M. Delatour) had several of these tumours of very large size, and at every contraction of the sphincter ani, the blood issued from them *per saltum*."—(*Hist. Phil. obs.* 212.) Montegre has likewise seen two instances in which the blood spouted out of the tumours in a continued stream.—(*Dict. des Sciences Méd. t.* 20, *p.* 453.) And Richerand mentions a merchant who lived to the age of eighty-nine, quite free from infirmity, and whose good health was ascribed to periodical bleedings from piles, during fifty years of his life; the evacuation being very regular, and so profuse, that the blood was thrown some distance, as from a vein opened in phlebotomy.—(See *Nosogr. Chir.*) If many piles were not either varices, or cysts in direct communication with the large veins of the rectum, Petit would not have succeeded in taking blood from them by puncture, as he often did in lieu of the ordinary mode of venesection.—(*Mal. Chir. t.* 2, *p.* 134.)

Hemorrhoids vary in number, size, form, and situation: some being *external*; others *internal*; and some hardly larger than a pea, while others exceed a hen's egg in size. Sometimes they bring on very serious complaints, either by bursting and discharging blood so profusely as dangerously to reduce the patient; or by exciting inflammation of the adjacent parts, and causing abscesses and fistulæ; or, lastly, by becoming strangulated by the contraction of the sphincter ani, so as to occasion severe pain. Piles which bleed but little are not of much consequence; but those which bleed profusely cause violent pain, or which induce inflammation and all its effects, demand the greatest attention. Lieutaud mentions a person who lost three quarts of blood from some piles in the course of a couple of days; and both Arius and the celebrated philosopher Copernicus are said to have bled to death in this manner.

I do not know what credit ought to be given to the extraordinary case cited by Panaroli, in which a Spanish nobleman voided every day, for four years, a pint of blood from some hemorrhoids, and yet enjoyed perfect health!—(See *Obs. Chir. pentec.* 2, *obs.* 46.) For other curious facts of this nature, see *Dict. des Sciences Méd. t.* 20, *p.* 458.

As Mr. Howship remarks, hemorrhoidal tumours, when connected with inflammation, are very painful. "The patient can then neither walk, ride, nor sit; the only tolerable state being that of rest in the reclined position. Should he, during the continuance of inflammation, be obliged to pass a motion, the distress is extreme. With these symptoms, there is generally more or less feverish heat and restlessness, now and then delirium."—(*On Diseases of the Lower Intestines, p* 208, *ed.* 3.)

In general, when piles are situated far up the rectum, they are less painful than when low down, and sometimes the patient is not conscious of having them till he begins to void blood from the rectum. In the former case, the veins or tumours are surrounded by soft and yielding substances, which do not make

any painful pressure on them; but when they are situated towards the anus, they often suffer painful constriction from the action of the sphincter muscle. Mr. Heaviside met with two examples where hemorrhoidal swellings were attacked with inflammation, and so violently strangulated by the spasmodic action of the sphincter ani, that the parts underwent a spontaneous mortification, and a radical cure was the result.—(*J. Howship on Diseases of the Lower Intestines, &c. p.* 210, *ed.* 3.)

With regard to the cause of hemorrhoids, any thing capable of retarding the return of blood through the hemorrhoidal veins may occasion the disease. The pressure of the gravid uterus, costiveness, and the frequent retention of hardened feces in the rectum, are very frequent causes. Persons who lead sedentary lives are often troubled with the complaint. Women are more subject to piles than men.

The pressure of an enlarged liver, or of water accumulated in the cavity of the peritoneum, may occasion piles.

I have adverted to the opinion of Montegre, that hemorrhoids depend upon a determination of blood to the lower part of the rectum; which sentiment is perhaps correct in cases where the disease arises from irritation in that bowel, or the neighbouring parts.

When these tumours are produced by the pressure of the gravid uterus, no cure can be expected till after delivery, when one generally follows spontaneously. Also, when piles are an effect of dropsy, they cannot get well before the pressure of the fluid in the abdomen has been removed by tapping. Gently laxative medicines and a horizontal position of the body commonly alleviate the uneasiness resulting from hemorrhoids. The application of an ointment composed of equal parts of the powder of oak-galls and of elder ointment or hog's lard contributes to the same beneficial effect. The application of warm water by means of a bidet, or semicupium, is also frequently productive of great ease. When piles are constricted by the sphincter ani muscle, the pain may often be at once removed by pushing the swellings up the rectum, and using fomentations or even the warm bath. Mr. Howship, in cases where the disposition to spasm in the sphincter is connected with high irritability in the bowel, recommends the introduction of a metallic bougie for a certain length of time, the size of the instrument and frequency of repetition of the operation being duly regulated.—(*On Diseases of the Lower Intestines, &c. p.* 214, *ed.* 3.) When the disease is in a state of inflammation, leeches applied to the vicinity of the anus, and puncturing the dilated hemorrhoidal vessels with a lancet, for the purpose of taking away blood, and the application of cold lotions, are measures occasionally employed to procure ease. The usefulness of leeches was particularly noticed by Schmucker.—(*Vermischte Chir. Schriften, b.* 1, *p.* 107.) Petit preferred the lancet.

According to Mr. Howship, when there is "frequent hemorrhage from the veins within the sphincter, with perhaps little or no external tumour, one of the best means of relief is the metallic bougie, regulated by the patient's feelings, and also by the promptitude with which inflammation and consolidation take place."—(*On Diseases of the Lower Intestines, &c. p.* 215, *ed.* 3.)

When the number and size of hemorrhoids are so considerable, as materially to obstruct the discharge of the feces; when they are severely painful, and subject to profuse bleedings; when the patient is disabled from following his usual occupations; and when the above means afford insufficient relief, the surgeon should recommend their removal.

The extirpation of piles with the actual cautery and caustics, as practised by the old surgeons, is now altogether relinquished. The only plan ever followed in the present state of surgery is, either to cut the tumours off with a pair of scissors or knife, or to apply a tight ligature round their base, so as to cause them to slough away. If possible, the opportunity of doing either of these operations should always be taken when the disease is in a tolerably quiet state.

When piles are to be cut off, and they are not sufficiently visible, the patient must first strain, as at stool, in order to make the swellings more apparent. With the aid of a pair of directing forceps, the skin covering the hemorrhoids is then to be separated from them with the knife, but not cut away, and the tumours being taken hold of with a tenaculum, are to be removed. Sabatier states, that saving the skin is very essential, for any hemorrhage which may arise can then be more easily suppressed; and when there are several hemorrhoids to be extirpated, the loss of substance about the anus will be less, and, of course, the patient will not be so liable to a contraction of this part, which is sometimes a very great affliction.

Previously to the performance of any operation, Mr. Abernethy endeavours to bring the bowels into a more regular state, and takes care to clear them with any medicine found by experience to answer the purpose without inducing a continuance of irritation and purging. "The bowel being everted to the utmost by the efforts used in evacuating the feces, and the parts cleansed by bathing with tepid water, the piles should be taken hold of with a double hook and removed with a pair of scissors. A protruded and thickened plait of the bowel may be removed in the same way; but I think it is best to use the bistoury in removing it, because the depth to which the scissors may cut is uncertain. The incision made by the knife resembles two curved lines joined at each extremity." The direction of the incision, both for the removal of piles, and that of plaits, he says, should be longitudinal in the direction of the bowel. When there is a transverse fold of the bowel of considerable extent, he prefers taking away two elliptical portions in the long axis of the rectum.—(See *Abernethy's Surgical Works, vol.* 2, *p.* 239.)

As I have explained in the former part of this work (see *Anus, Prolapsus of*), the late Mr. Hey used to remove these extensive diseased folds about the verge of the anus, with great success. J. L. Petit followed the same practice (*Mal. Chir. t.* 2, *p.* 134), and more recently Mr. Kirby.—(*Obs. on the Hemorrhoidal Excrescence, Lond.* 1817.)

The late Mr. Ware published some remarks, the tenor of which is to prove, that when there are several hemorrhoids, the removal of one or two of the most painful of them, with a pair of scissors, will afford effectual relief.

The excision of piles is occasionally followed by dangerous bleeding, as is exemplified in a case related by Petit. A patient had some hemorrhoids, which were supposed to be external, while they were only temporarily protruded. Almost immediately after they had been cut off, the skin which had supported them was drawn inwards. An internal hemorrhage ensued, which could not be suppressed, and proved fatal in less than five hours. The rectum and colon were found full of black, coagulated blood. Sir E. Home speaks also of some instances within his knowledge, where, after the removal of internal piles with the knife, the bleeding endangered life.—(*On Ulcers, p.* 365.)

If the bleeding should be troublesome, and proceed from vessels within the rectum, the best plan would be to distend the gut with a suitable piece of sponge, so as to make pressure on the wound. Cold should also be applied to the sacrum and nates.

The removal of hemorrhoids with a ligature may generally be done with sufficient safety; but still it has its inconveniences, though they are not constant. Petit frequently practised this method without any ill effects. In other instances he had reason to repent of having adopted it. A woman, in whom he had tied three hemorrhoids with narrow pedicles, which were favourably situated for this operation, did not at first experience a great deal of pain. However, five hours afterward he was informed that she suffered violent colic pains, which extended along the colon. She was bled four times without material relief. At last Petit cut the ligatures, which could not be loosened, in consequence of their being concealed so deeply in the substance of the swollen parts. The pain very soon subsided. The ligatures had only been applied four-and-twenty hours, but the piles had become black, and the skin covering their bases was cut through. Petit then removed them without the least effusion of blood.

Petit also relates a case in which a patient, after having had some piles tied, died of symptoms resembling those which take place in cases of strangulated hernia, notwithstanding the ligatures had been cut, as in the foregoing instance. After these two cases, Petit abandoned the practice of tying hemorrhoids. Mr. Kirby has mentioned two cases proving the ill effects sometimes arising from the ligature of piles: in one of these examples, the patient's life was saved with great difficulty; and in the other the operation was followed by

tetanus and death.—(*Obs. on the Treatment of certain severe Forms of Hemorrhoidal Excrescence*, p. 1—3, 8vo. *Lond.* 1817.)

Mr. Howship, who prefers the use of the ligature, observes, that in performing the operation, it is not necessary to take up all the tumours; but that, if there are five or six, the tying of two or three of the largest will generally produce such a change in the texture of the rest, as will secure the patient from any return of the disease. After the ligatures are detached, he discontinues the fomentations and applies cold lotions.—(*On Diseases of the Lower Intestines, &c. p.* 216, *ed.* 3.)

I believe, on the whole, that it is best to remove hemorrhoids with a knife, except when they are situated high up the rectum, where the veins are of large size and likely to bleed profusely. If a tumour so situated should absolutely require removal, which can rarely happen, a ligature might be put round its base with the aid of a double cannula. When the base of the tumour, however, is large, admits of being brought into view, and the surgeon prefers tying it, he should pass a needle, armed with a strong double ligature, through the root of the hemorrhoid, and tie one part of this ligature firmly over one side of the swelling and the other over the opposite side. When the base of the tumour is narrow, and the ligature is preferred, the part may be tied at once, without passing a double ligature through its middle.

Old hemorrhoids, which have been repeatedly in a state of inflammation, at length acquire a considerable degree of hardness. The internal membrane of the rectum becomes thickened, loses its natural softness, and forms a kind of cyst which prevents the tumour from bursting and bleeding.—(See *Theden, Progrès de la Chirurgie, sect.* 4, *p.* 73.) In the end, it ulcerates and pours out a fetid discharge. Its size cannot now be lessened by the use of emollient applications; and its excision is indispensably necessary.—(See *Lassus, Pathologie Chir. t.* 1, *p.* 336.)

An opinion has commonly prevailed, that the bleeding from piles is of a salutary or critical nature; an evacuation, by which some peccant or morbid matter is thrown off from the body. Hence, many patients have been advised to submit to all the pain and uneasiness which the disease occasions, rather than seek a cure. If the fact, that some patients lose their health after their piles have been cured, be received as sufficient proof of the disease having had a salutary effect, the doctrine must remain fully established. But before this inference should be drawn, it ought to be known whether the frequency of the fact is such as to warrant the conclusion; for it is not to be supposed that the removal of piles places the patient altogether beyond the reach of disease and illness; and no one will deny, that such operation frequently leads to improvement of the health. Were a patient to appear to suffer from the cessation of an habitual bleeding from piles, leeches and even cupping-glasses might be applied.

A

DICTIONARY

OF

PRACTICAL SURGERY.

SURGICAL DICTIONARY.

H

HE'RNIA. (From ἔρνος, a branch, from its protruding forward.) Surgeons understand, by the term *hernia*, a tumour, formed by the protrusion of some of the viscera of the abdomen, out of that cavity, into a kind of sac, composed of the portion of peritoneum, which is pushed before them. However, there are certainly cas s which will not be comprehended in this definition; either because the parts are not protruded at all, or have no hernial sac. It is only in rare cases, that the sac is wanting; as, for example, when the hernia has been produced by the operation of great violence, or has been preceded by a wound of the abdominal parietes, or an attempt at a radical cure has been made with caustic. The sac is also sometimes rendered imperfect by laceration or ulceration. Some viscera, which occasionally protrude, are not included in the peritoneum, as the bladder and cœcum; and when they are considerably displaced, they draw after them the portion of peritoneum connected with them, which forms a sac into which other bowels may fall.

"The brilliant progress which surgery has made in modern times (says Scarpa) is, properly speaking, only the result of pathological anatomy; that is to say, of exact comparisons of the natural state of our organs with their different diseases, which may depend upon an alteration of texture, a derangement of functions, a solution of continuity, or a change of situation. It is from morbid anatomy, that the most rational curative methods, with which modern surgery is enriched, are deduced as so many corollaries; methods, to which we are also indebted for the perfection of operations.

'There are indeed a certain number of surgical operations, for the prompt and safe execution of which mere anatomical knowledge will suffice: but, in many others, the surgeon cannot promise himself success, even though he be well acquainted with anatomy, unless he has particularly studied the numerous changes of position, and alterations of texture, of which the parts upon which he is about to operate are susceptible. If he has not the requisite information upon all these points, false appearances may deceive his judgment, and make him commit mistakes, sometimes of very serious and irreparable kind.

"In order to have a convincing proof of this truth, it will be sufficient to take a view of the different species of hernia, and their numerous complications. Assuredly, no anatomist would believe, that the intestine cœcum, naturally fixed in the right ilium, and the urinary bladder, situated at the bottom of the pelvis, could undergo without being torn, so considerable a displacement as to protrude through the abdominal ring, and descend even into the scrotum; that the same intestine, the cœcum, could pass from the right iliac region to the umbilicus, protrude at this opening, and form an umbilical hernia; that the right colon could have been found protruded from the abdomen at the left abdominal ring, and the left colon through the right one; that the liver, spleen, and ovary could sometimes form the contents of umbilical, inguinal, and femoral herniæ; that the cœcum could engage itself within the colon, and even protrude at the anus; that the stomach could be forced through the diaphragm, and form a hernia within the chest; that the omentum, or intestine, or both these parts together, could sometimes escape from the belly through the foramen ovale, or sacro-ischiatic notch of the pelvis; that a noose of small intestine, after being engaged in the abdominal ring, or under the femoral arch, could suffer the most violent strangulation, without the course of the intestinal matter being intercepted; lastly, that in certain circumstances, the intestine and omentum could be in immediate contact with the testicle, within the tunica vaginalis, without the least laceration of this latter membrane. These and several other analogous facts (says Scarpa) are so surprising, that they would yet be regarded as incredible, had they not been proved by numerous observations on individuals affected with hernia: their possibility (repeats this experienced professor) would not even have been suspected, either by the anatomist or physiologist."—(See *Scarpa, Traité des Hernies, Pref.*)

The parts of the body, where herniæ most frequently make their appearance, are the groin, the navel, the labia pudendi, and the upper and forepart of the thigh; they do also occur at every point of the anterior part of the abdomen; and there are several less common instances, in which hernial tumours present themselves at the foramen ovale; in the perineum; in the vagina; at the ischiatic notch, &c.

The parts, which, by being thrust forth from the cavity in which they ought naturally to remain, mostly produce herniæ, are either a portion of the omentum, or a part of the intestinal canal, or both together. But the stomach, the liver, spleen, uterus, ovaries, bladder, &c. have been known to form the contents of some hernial tumours. The small intestine is more frequently protruded than the large, and the ilium more frequently than the jejunum, in consequence of its greater proximity to the ring and crural arch. A part only of the diameter of the tube is sometimes included in a hernia; any larger quantity may descend, from a single fold to the whole moveable portion of the canal.—(See *Lawrence on Ruptures, p. 5, ed. 4.*)

From these two circumstances of situation and contents, are derived all the different appellations by which herniæ are distinguished. If a portion of intestine alone form the contents of the tumour, the case is called *enterocele;* if a piece of omentum only, *epiplocele;* and if both intestine and omentum contribute to the formation of the tumour, it is called an *entero-epiplocele.* When the contents of a hernia protrude at the abdominal ring, but only pass as low as the groin, or labium pudendi, the case receives the name of *bubonocele* or *inguinal hernia;* but if the parts descend into the scrotum, it is called an *oscheocele* or *scrotal hernia.* The *crural* or *femoral hernia* is the name given to that which takes place below Poupart's ligament. When the bowels protrude at the navel, the case is named an *exomphales* or *umbilical hernia;* and *ventral* is the epithet given to the swelling, when it occurs at any other promiscuous part of the front of the abdomen. The *congenital rupture* is a very particular case, in which the protruded viscera are not covered with a common hernial sac of peritoneum, but are lodged in the cavity of the tunica vaginalis, in contact with the testicle; and, as must be obvious, it is not named, like herniæ in general, from its situation, or contents, but from the circumstance of its existing from the time of birth.

When the protruded bowels lie quietly in the sac, and admit of being readily put back into the abdomen, the case is termed a *reducible hernia;* and when they suffer no constriction, yet cannot be put back, owing to adhesions, or their large size in relation to the aperture through which they have to pass, the hernia is termed *irreducible.* An *incarcerated* or *strangulated hernia*, signifies one, which not only cannot be reduced, but suffers constriction; so that, if a piece of

intestine be protruded, the pressure, to which it is subjected, stops the passage of its contents towards the anus, excites inflammation of the bowel, and brings on a train of alarming, and often fatal, consequences.

The causes of herniæ are either *predisposing* or *exciting*. Among the former, writers mention a preternaturally large size of the openings, at which the bowels are liable to protrude; a weakness and relaxation of the margins of these apertures; a preternatural laxity of the peritoneum; an unusually long mesentery, or omentum, &c. With regard to the abdominal ring, the transverse tendinous fibres, which naturally cross and strengthen its upper and outer part, are much weaker in some subjects than others. No idea seems more prevalent in books, than that taking a good deal of oil with our food, is conducive to the formation of hernial diseases. Some of the alleged predisposing causes may justly excite skepticism; but several circumstances tend to prove, that a natural deficiency of resistance, in any part of the parietes of the abdomen, promotes the occurrence of hernia. Hence, persons who have had the peritoneum wounded are very liable to the present disease (*Richerand, Nosogr. Chir. t.* 3, *p.* 317; *Schmucker, Vermischte Chir. Schriften, b.* 1, *p.* 197); and men are much more liable than women to inguinal hernia, evidently from the larger size of the abdominal ring; while, in women, as there is a larger space for the protrusion of the viscera, below Poupart's ligament, they are more exposed than men to femoral herniæ.

With regard to the *exciting* causes, our knowledge is involved in less doubt. The grand cause of this kind is the powerful action of the abdominal muscles and diaphragm on the viscera. In feats of agility, such as jumping, &c. the pressure which the contents of the abdomen must often encounter, sufficiently accounts for their protruding at any part, where the abdominal parietes do not make adequate resistance. The same consideration explains why herniæ very often take place in lifting and carrying heavy weights, running, vomiting, straining at stool, parturition, &c. and in people who inhabit mountainous countries.

The diminution of the capacity of the abdomen, by the action of the abdominal muscles and diaphragm, in many occasional exertions, must take place in every body, by reason of the common habits and necessities of life. But, as only a certain number of persons meet with the disease, it is fair to infer, that either the exciting causes must operate with greater force in them, than in the generality of people, or else that their abdominal parietes have not been capable of the ordinary degree of resistance. Many patients, who meet with herniæ in making violent efforts and exertions, may be in the former circumstance; while others, whose viscera protrude from such trivial things as coughing, sneezing, crying, &c. must be considered as being under the influence of some predisposing cause. A gentleman, who has gained great honour by a most valuable treatise on hernia, remarks, that "herniæ, which originate in predisposition, generally come on gradually, and almost imperceptibly; while those which are produced by bodily exertions, are formed suddenly, and by the immediate action of the exciting cause. The occurrence of the complaint is often indicated, in the first instance, by a fulness, combined with a sense of weakness, about the abdominal ring. The swelling is increased by any action of the respiratory muscles, and disappears on pressure, and in the recumbent position of the body. It gradually finds its way through the tendon of the external oblique muscle, into the groin, and afterward into the scrotum. When a hernia takes place suddenly, it is generally attended with a sensation of something giving way at the part, and with pain."—(*Lawrence on Ruptures, p.* 42, *edit.* 4.)

Upon the subject of the immediate cause of herniæ, it is observed by Scarpa, that several distinguished modern surgeons, as, for instance, Warton (*Adenograph. cap.* 11), Benevoli (*Dissertazioni Chirurgische*, 1), Rossius (*Acta Nat. Cur. t.* 2, *obs.* 178), Brendel (*De Herniarum Natalibus*), and Morgagni (*De Sed. et Caus. Morb. epist.* 43, *art.* 13), consider a relaxation and elongation of the mesentery as the principal cause of herniæ in general, and of the bubonocele in particular. Hence, say they, the whole mass of intestines, or only a portion of an intestine, descends against the inner orifice of the inguinal ring, presses against this opening, and gradually makes its way out of the abdomen. In examining this pathological point without prejudice, it is incontestable, says Scarpa, that an intestine cannot be moved beyond its natural limits, unless that part of the mesentery, which retains and fixes the bowel in its proper place, be at the same time elongated. But it does not follow from this, that a relaxation of the mesentery must precede the displacement of the intestine. It appears to Scarpa much more probable, that these two events are simultaneous, and depend upon one and the same cause.

"In the healthy state, the abdomen, considered altogether, is submitted to two opposite forces, which reciprocally balance each other. One is the pressure of the viscera against the abdominal parietes; the other is the reaction of these same parietes upon the viscera, which they contain. If these two forces were in perfect equilibrium in all individuals, and under all the circumstances of life, we should not be in the least subject to herniæ. If, when the equilibrium has been broken, every point of the parietes of the belly were to yield equally to the impulse of the viscera, an increase of the volume of the whole abdomen would be the consequence; but a true hernia would never happen. The cavity of the abdomen is always completely full. The containing and contained parts react upon, and reciprocally compress, one another. It is by the effect of this moderate, but equal and unremitting pressure, that all the viscera mutually support each other. Without it, the ligaments of the liver, those of the spleen, and the various membranous bands of the intestines in general, would only be feeble means for fixing such parts in their respective situations. But there are certain points of the abdominal parietes which naturally present much less resistance than others, and which react with much less power against the pressure made from within outwards by the abdominal viscera. Such is particularly the part which extends from the pubes to the anterior superior spinous process of the ilium. This relative weakness of some points of the abdominal parietes is very marked in certain individuals, in consequence of a defect of organization. It may also be increased by internal or external causes, which are as various as they are numerous. When, in one of these cases, the pressure made by the viscera is unusually increased, as happens in a violent effort, a defect in the equilibrium between the two forces above mentioned is occasioned; that is to say, the reaction of the abdominal parietes is no longer proportioned, at least at certain points, to the force of the impulse of the viscera. The conjoined powers of the abdominal muscles, diaphragm, and levator ani, are then directed and concentrated against the most feeble point of the abdomen, towards which they propel the nearest viscus, or that which, from its moveableness, is the most liable to displacement. If such viscus should happen to be the noose of an intestine, it is evident, that the power, which tends to make it protrude from the belly, must at the same time act upon the corresponding portion of the mesentery; and the intestine, in passing through the parietes of the abdomen, drags the mesentery after it, and makes this membrane yield and become elongated. When the displaced viscera meet with little resistance on the part of the parietes of the abdomen, the hernia is quickly formed, and the elongation of the mesentery occurs with equal celerity. We have an example of this in the inguinal congenital hernia: in this case the intestine is, in some measure, precipitated into a sac previously prepared for its reception. On the contrary, in the ordinary inguinal hernia, a totally different disposition of the parts renders the progress of the disease much slower. In most instances, the hernia is not formed immediately the equilibrium between the impulse of the viscera and the reaction of the abdominal parietes is broken. But in the groin, a slight elevation is first observed, in the direction from the anterior superior spinous process of the ilium towards the inguinal ring. Some time afterward, when the intestine has made its appearance on the outside of the ring, the enlargement of the hernia, and the elongation of the mesentery, make much more rapid, though always simultaneous, progress."

"Numerous practical observations (says Scarpa) concur in proving, that we must not search for the immediate cause of herniæ in the relaxation of the mesentery, but rather in a want of equilibrium between

the pressure of the viscera and the resistance of one or several points of the abdominal parietes. Indeed, herniæ are seen occurring from the slightest causes in infants, in whom the neck of the tunica vaginalis is not speedily obliterated, and in individuals who, from being fat, have all on a sudden become extremely thin. Such women as have had children are more subject to the disease than others. Persons also of both sexes, who carry considerable burdens, or who play upon wind instruments, or who have suffered a forcible contusion of the abdomen, are particularly exposed to the disorder, even though there be not the least reason for suspecting in them a relaxation of the mesentery. Vaginal herniæ which arise after difficult labours, afford another proof of the same truth: their cause is owing to a laxity and weakness of the parietes of the vagina, which, not being capable of making any farther resistance to the pressure of the viscera, situated in the cavity of the pelvis, at length suffer these parts to protrude.

"With respect to the second proposition, that during the formation of a hernia, the combined force of all the abdominal muscles is, as it were, directed and concentrated against the most feeble point of the parietes, we see a proof of it in a fact that occurs to our observation every day. In order to convince ourselves of this, we need only notice what happens in individuals afflicted with herniæ: if they cough, or sneeze, or make the slightest effort, they instantly find the size of the swelling increased, and hasten to support the part with their hand. During the slightest efforts, which render the herniæ larger, it is also indisputable, that the mesentery is elongated in the same proportion as the intestine protrudes. All the viscera have such a tendency to be displaced and carried towards the weakest point of the parietes of the abdomen, that even those which are naturally the most distant from it, and are the most firmly fixed by the folds of the mesentery, may in their turn descend into the herniæ. Anatomical knowledge alone would never have led us to entertain a suspicion of the possibility of these occurrences. Sandifort and Paletta have found, in an umbilical hernia, the cœcum, with a portion of the ilium and colon.—(*Obs. Pathol. cap.* 4; and *Nova Gubernaculi Testis Descriptio.*) Mauchart, Camper, and Bose have met with the cœcum in an inguinal hernia of the left side.—(*De Hern. Incarc. in Halleri Disput. Chirurg. tom.* 3; *Demonstrat. Anat. Patholog. lib.* 2, *p.* 18; *et Animadvers. de Hern. Inguin. p.* 5.) Lassus has seen the left colon protrude at the right inguinal ring.—(*Médecine Opératoire, t.* 1, *p.* 173.) If it be proved by all these facts, that such viscera as are the most closely united to the great sac of the peritoneum and neighbouring parts, are nevertheless liable to form herniæ; and if such displacements cannot happen without a considerable elongation of the membranous bands fixing these bowels in their natural situation; how can we refuse to admit, that a noose of intestine, pushed by degrees through the inguinal ring, drags along with it the corresponding portion of the mesentery? In order to explain this event, there is no necessity for supposing a partial relaxation of the mesentery."—(*Traité Pratique des Hernies, par A. Scarpa, trad. de l'Italien, p.* 37—43.)

The same causes, which first produced the complaint, or others of an analogous nature, as Mr. Lawrence has noticed, are constantly tending to promote its increase. The tumour becomes larger, in proportion as the pressure against the hernial sac is stronger, and more frequent. Hence, the great size which it often attains in persons constantly pursuing laborious occupations. Its increase will also be in proportion to the less considerable resistance of the parts in which it is situated. Hence, the magnitude of scrotal ruptures, and the generally small size of a femoral hernia. The size of a hernia is likewise in part dependent upon the largeness and weakness of the opening, through which the protrusion happens. Hence, inguinal ruptures are usually much larger than those called femoral, or crural. The looseness of the cellular connexion of the peritoneum is another cause of the disposition of a hernia to attain a considerable magnitude; while the shortness and closeness of the same uniting medium operate, in particular cases, as a check to the enlargement of the tumour, as is exemplified in herniæ of the linea alba, which are generally small. When the sac, after it has passed the parietes of the abdomen, is situated among cellular, or adipous substance, it expands equally in all directions, and forms a nearly spherical tumour, being, however, generally rather flattened, as in umbilical and crural herniæ. If it protrude through a canal, it is nearly cylindrical, as in incipient inguinal herniæ; and even in those which have passed the ring, and are still confined by the sheath of the spermatic cord. The fundus of the sac enlarges as it descends into the scrotum, and thus, in almost all scrotal cases, the swelling becomes pyriform. Irregularities of shape often take place from the extension of the membrane in directions presenting the least resistance. At the first moment of the occurrence of a hernia of sudden formation, the protruded peritoneum is unconnected to the parts among which it lies; but adhesions take place so quickly, that the sac is found universally connected to the contiguous parts, even in a rupture of two or three days' standing. These adhesions prevent the return of the sac into the abdomen, when the contents of the swelling are replaced. The peritoneum, which immediately surrounds the protruded viscera, generally retains the same thin and delicate structure which characterizes that membrane in its natural situation. It is covered by other investments, varying in thickness and structure, according to the part in which the swelling is formed, and the size and duration of the tumour, &c.—(See *Lawrence on Ruptures, p.* 18, *&c. edit.* 4.)

Many interesting circumstances, in relation to hernial sacs, have been satisfactorily explained by Cloquet; and some of them are noticed in Mr. Lawrence's work. "If the causes which have produced the hernia continue to operate, and further descent of the peritoneum be prevented by its strong adhesion to the tendinous opening, the sac becomes thin by distention. It may give way partially by a kind of laceration, and thus become irregular in figure, presenting an appearance of small cysts, or secondary cavities. On the contrary, when the neck does not adhere so strongly, and the mouth of the sac forms a thickened ring, the renewed action of pressure may make the ring descend, and a fresh one will form at the new mouth of the sac. This process may be again repeated; and thus the sac presents one or more constrictions, by which the protruded parts may be compressed, and even strangulated. Inguinal and scrotal ruptures are almost the only cases in which this occurrence can take place. When a hernia passes through a canal, a thickened ring may be formed at both orifices of the canal. If a hernial sac has been formed, and its mouth become thickened, a new protrusion may take place by the side of it: this may occur again: and thus we may have sacs composed of two lateral cavities, or consisting of two or more secondary openings into one principal protrusion; or, the original serous cavity may be contracted, and form a small appendix to the subsequent protrusion."—(See *Lawrence on Ruptures, p.* 26; and *Cloquet's Recherches sur les Causes, &c. des Hernies.*)

Herniæ are more frequent on the right, than on the left side of the body. This fact, as Mr. Lawrence has remarked, does not depend on any disparity in size, between the apertures of the two sides, but must be referred to the employment of the right side in those offices of life which require the most powerful exertion.—(*On Ruptures, p.* 33, *ed.* 4.) This subject has been particularly considered by Cloquet.—(See *Recherches sur les Causes et l'Anatomie des Hernies Abdominales p.* 10, *&c. 4to. Paris*, 1819.)

The general symptoms of a hernia, which is reducible, and free from strangulation, are, an indolent tumour at some point of the abdomen, most frequently descending out of the abdominal ring, or from just below Poupart's ligament, or else out of the navel; but, occasionally, from various other situations, as will be presently explained. The swelling often originates suddenly, except in the circumstances above related, and it is subject to a change of size, being smaller when the patient lies down on his back, and larger when he stands up, or holds his breath. It frequently diminishes when pressed, and grows large again when the pressure is removed. Its size and tension often increase after a meal, or when the patient is flatulent. In consequence of the unnatural situation of the bowels, many patients with hernia are occasionally troubled with colic, constipation, and vomiting. Sometimes, however, the functions of the viscera seem to suffer little or no interruption.

Sometimes the contained parts may be known by the symptoms. But, as Mr. Lawrence justly remarks, this discrimination is often difficult, and even impossible, when the hernia is old, large, and very tense: for, in cases of this description, the viscera experience considerable changes in their figure and state, while the thickened hernial sac prevents an accurate examination by the hand.—(*On Ruptures*, *p.* 46, *ed.* 4.)

If the case be an *enterocele*, and the portion of intestine be small, the tumour is small in proportion; but, though small, if the gut be distended with wind, inflamed, or have any degree of stricture made on it, it will be tense, resist the impression of the finger, and give pain upon being handled On the contrary, if there be no stricture, and the intestine suffer no degree of inflammation, let the prolapsed piece be of what length it may, and the tumour of whatever size, the tension will be little, and no pain will attend the handling of it; upon the patient's coughing, it will feel as if it were blown into; and, in general, it will be found very easily returnable.—(*Pott.*) A gurgling noise is often made when the bowel is ascending. An enterocele is also generally characterized by the uniformity of its surface and its elasticity.

If the hernia be an *epiplocele*, or one of the omental kind, the tumour has a more flabby, and a more unequal feel; it is in general perfectly indolent, is more compressible, and (if in the scrotum) is more oblong, and less round, than the swelling occasioned in the same situation by an intestinal hernia; and, if the quantity be large, and the patient adult, it is, in some measure, distinguishable by its greater weight. In very young subjects, the contents of a hernia are generally intestine, and but seldom omentum.—(*A. Cooper, Lectures*, *vol.* 3, *p.* 8.)

If the case be an *entero-epiplocele*, that is, one consisting of both intestine and omentum, the characteristic marks will be less clear than in either of the simple cases; but the disease may easily be distinguished from every other one, by any body in the habit of making the examination.—(*Pott*, *p.* 28.)

As the smooth slippery surface of the intestine generally makes its reduction easier than that of the omentum, we may infer, with Mr. Lawrence, "that if a portion of the contents slip up quickly and with noise, leaving behind something which is less easily reduced, the case is probably an entero-epiplocele."—(*Op. cit. ed.* 4, *p.* 47.)

On the subject of prognosis, Mr. Pott remarks, that the age and constitution of the subject, the date of the disease, its being free or not free from stricture or inflammation, the symptoms which attend it, and the probability or improbability of its being returnable, necessarily produce much variety.

If the subject be an infant, the case is not often attended with much difficulty or hazard, the reduction being easy as well as the descent; and though from neglect, or inattention, the bowel may fall down again, yet it is as easily replaced, and mischief seldom produced: Mr. Pott says seldom, because he has seen an infant, one year old, die of a strangulated hernia, which had not been down two days, with all the symptoms of mortified intestine. For other examples of strangulated hernia in very young infants, refer to *Gooch's Chir. Works*, *vol.* 2, *p.* 33; *Lawrence on Ruptures*, *p.* 77, *edit.* 4; *Edin. Med. and Surgical Journal*, *vol.* 3, *p.* 470, *&c.*

"If the patient be adult, and in the vigour of life, the consequences of neglect, or of mal-treatment, are more to be feared than at any other time, for reasons too obvious to need relating. The great and principal mischief to be apprehended, in an intestinal hernia, is an inflammation of the gut, and an obstruction to the passage of the aliment and feces through it; which inflammation and obstruction are generally produced by a stricture made on the intestine. In very old people, the symptoms do not usually make such rapid progress, both on account of the laxity of their frame, and their more languid circulation: and also because their ruptures are most frequently of ancient date, and the passage a good deal dilated: but then, on the other hand, it should also be remembered, that they are by no means exempt from inflammatory symptoms; and that if such should come on, the infirmity of old age is no favourable circumstance in the treatment, which may become necessary."—(*Pott.*)

If the disease be recent, and the patient young, immediate reduction, and constant care to prevent another protrusion, are the only means whereby it is possible to obtain a perfect cure.

"If the disease be of long standing, has been neglected, or suffered to be frequently down, and has given little or no trouble, the aperture in the abdominal muscle, and the neck of the hernial sac, may both be presumed to be large; which circumstances in general render immediate reduction less necessary and less difficult, and also frustrate all rational expectation of a perfect cure. On the contrary, if the rupture be recent, or, though old, has generally been kept up, its immediate reduction is more absolutely necessary, as the risk of stricture is greater from the supposed smallness of the aperture, and narrowness of the sac. If the rupture be very large and ancient, the patient far advanced in life, the intestine not bound by any degree of stricture, but does its office in the scrotum regularly, and no other inconvenience be found to attend it, but what proceeds from its weight, it will in general be better not to attempt reduction, as it will, in these circumstances, most probably prove fruitless, and the handling of the parts, in the attempt, may so bruise and injure them as to do mischief."

With respect to the correctness of the advice here delivered, some doubt may be entertained, because, though it would certainly not be right to protract the attempts at reduction, so as to do mischief, it must be equally wrong to make no trial, whether the hernia is reducible or not; and if reducible, I should say, that it ought to be reduced without delay, and a truss applied. This opinion, however, seems to agree with the injunctions delivered by Pott in another place, as will be seen in the next section of this article.

With regard to the contents of a hernia, Mr. Pott observes, that "if it be a portion of omentum only, and has been gradually formed, it seldom occasions any bad symptoms, though its weight will sometimes render it very troublesome. But if it be produced suddenly, by effort or violence, that is, if a considerable piece of the caul by accident slip down at once, it will sometimes prove painful, and cause very disagreeable complaints; the connexion between the omentum, stomach, duodenum, &c. being such as to render the sudden descent of a large piece of the first sometimes productive of nausea, vomiting, colic, and all the disagreeable symptoms arising from the derangement of these viscera. When the piece of caul is engaged in such a degree of stricture as to prevent the circulation of blood through it, it will sometimes, by becoming gangrenous, be the occasion of very bad symptoms, and even of death, as I have more than once seen: and thus, as a mere omental hernia, it may sometimes be subject to great hazard But even though it should never be liable to the just-mentioned evil, that is, though the portion of the caul should remain uninjured in the scrotum, yet it renders the patient constantly liable to hazard from another quarter; it makes it every moment possible for a piece of intestine to slip into the same sac, and thereby add to the case all the trouble and all the danger arising from an intestinal rupture. It is by no means an uncommon thing for a piece of gut to be added to a rupture, which had for many years been merely omental, and for that piece to be strangulated, and require immediate help.

"An old omental hernia is often rendered not reducible, more by an alteration made in the state of the prolapsed piece of caul, than by its quantity. It is very common for that part of the omentum which passes through the neck of the sac to be compressed into a hard, smooth body, and all appearance of caul, while what is below in the scrotum is loose and expanded, and enjoys its natural texture: in this case, reduction is often impossible, from the mere figure of the part: and I have so often seen this, both in the living and the dead, that I am satisfied, that for one omental rupture, rendered irreducible by adhesions, many more become so from the cause above mentioned.

"In the sac of old omental ruptures that have been long down, and only suspended by a bag-truss, it is no very uncommon thing to have a pretty considerable quantity of fluid collected; this, in different states and circumstances of the disease, is of different colour and consistence, and seldom so much in quantity as to occasion any particular attention to it; but, on the other hand, it sometimes is so much in quantity as to become an additional disease to the original one. I

have more than once been obliged to let it out, in order to remove the inconvenience arising from its weight, and the distention of the scrotum, which I have also seen become gangrenous by the neglect of this operation.

"If the hernia be of the intestinal kind merely, and the portion of gut be small, the risk is greater, strangulation being more likely to happen in this case, and more productive of mischief, when it has happened: for the smaller the portion of gut is which is engaged, the tighter the tendon binds, and the more hazardous is the consequence. I have seen a fatal gangrene, in a bubonocele, which had not been formed forty-eight hours, and in which the piece of intestine was little more than half an inch."

Another observation made by Pott is, that "if the hernia be caused by a portion of the intestine ilium only, it is in general more easily reducible, than if a part of the colon has descended with it, which will also require more address and more patience in the attempt. The reduction of a mere intestinal hernia too (*cæteris paribus*) will always remain more practicable than that of a mere omental one, after it has attained to a certain size and state, as the part contained within the former is liable to less alteration of form than that within the latter; which alteration has already been mentioned as no unfrequent hinderance of the return of an old caul-rupture.

"Not that the parts within a mere intestinal hernia are absolutely exempt from such an alteration as may render their return into the belly impracticable, even where there is no stricture; for (says Pott) I have seen that part of the mesentery which has lain long in the neck of the sac of an old rupture, so considerably hardened and thickened, as to prove an insuperable obstacle to its reduction."

Upon the whole, this author infers, that an intestinal rupture is subject to worse symptoms, and a greater degree of hazard, than an omental one, though the latter is, by no means, so void of either as it was formerly supposed to be; that bad symptoms are more likely to attend a recent rupture, than one of ancient date; that the descent of a very small piece of intestine is more hazardous than that of a larger; and that the hernia, which consists of gut only, is in general attended with worse circumstances, than that which is made up of both gut and caul.—(See also *Lawrence on Ruptures*, *p.* 75, 76, *ed.* 4.)

Mr. Hey coincides with Pott, in thinking the prognosis more unfavourable when the tumour is small. "I think it is not a bad general rule, that the smaller the hernia, the less hope there is of reducing it by the taxis. Long-continued efforts to reduce a prolapsed intestine, are most likely to succeed in old and large hernias, when no adhesions have taken place."—(*Pract. Observ. in Surgery*, *p.* 203.)

It is correctly remarked by Mr. Lawrence, that "the danger is greatest, when a rupture is incarcerated at the moment of its formation. Herniæ, which arise spontaneously, and merely from predisposing weakness, seldom become strangulated: the stricture, in such cases, is never close, nor are the symptoms violent, because the parts concerned are weak and relaxed.

"The opening through which the parts protrude is narrower in some situations than in others; the progress of the case will therefore be more rapid, and the danger of the patient more urgent. The aperture is generally very small in femoral hernia: this kind of rupture in men, and the bubonocele in women, have a particularly narrow entrance. On the same grounds, femoral, inguinal, and umbilical ruptures are more dangerous than the ventral, perineal, or vaginal kinds." (*Treatise on Ruptures*, *p.* 75, *ed.* 4.)

TREATMENT OF A HERNIA CAPABLE OF EASY AND IMMEDIATE REDUCTION, AND NOT ATTENDED WITH ANY TROUBLESOME OR BAD SYMPTOMS.

"This case," says Pott, "is very frequently met with in infants, and sometimes in adults, and is too often neglected in both. In the former, as the descent seldom happens but when the infant strains to cry, and the gut is either easily put up, or returns *sua sponte*, as soon as the child becomes quiet, it often is either totally unattended to, or an attempt made to restrain it only by a bandage made of cloth or dimity, and which, being ineffectual for such purpose, lays the foundation for future trouble and mischief.

"This is, in great measure, owing to a common opinion, that a young infant cannot wear a steel truss; a generally prevailing error, and which ought to be corrected. There is no age at which such truss may not be worn, or ought not to be applied; it is, when well made and properly put on, not only perfectly safe and easy, but the only kind of bandage that can be depended upon; and as a radical cure depends greatly on the thinness of the hernial sac, and its being capable of being so compressed as possibly to unite, and thereby entirely close the passage from the belly, it must therefore appear to every one who will give himself the trouble of thinking on the subject, that the fewer times the parts have made a descent, and the smaller and finer the elongation of the peritoneum is, the greater the probability of such cure must be.

"The same method of acting must, for the same reasons, be good in every age, in which a radical cure may reasonably be expected; that is, the prolapsed parts cannot be too soon returned, nor too carefully prevented from falling down again; every new descent rendering a cure both more distant and more uncertain.

"As soon as the parts are returned, the truss should be immediately put on, and worn without remission; care being taken, especially if the patient be an infant, to keep the parts upon which it presses constantly washed, to prevent galling.

"It can hardly be necessary to say, that the surgeon should be careful to see that the truss fits, as his success and reputation depend on such care. A truss which does not press enough is worse than none at all, as it occasions loss of time, and deceives the patient or his friends; and one which presses too much, or on an improper part, gives pain and trouble, by producing an inflammation and swelling of the spermatic cord, and sometimes of the testicle.

"In adults, whose ruptures are of long standing, and accustomed to frequent descent, the hernial sac is generally firm and thick, and the aperture in the tendon of the abdominal muscle large; the freedom and ease with which the parts return into the belly when the patient is in a supine posture, and the little pain which attends a rupture of this kind, often render the persons who labour under it careless: but all such should be informed, that they are in constant danger of such alteration in their complaint, as may put them into great hazard, and perhaps destroy them. The passage from the belly being open, the quantity of intestine in the hernial sac is always liable to be increased, and, when down, to be bound by a stricture. An inflammation of that portion of the gut which is down, or such obstruction in it as may distend and enlarge it, may at all times produce such complaints as may put the life of the patient in imminent danger; and therefore, notwithstanding this kind of hernia may have been borne for a great length of time, without having proved either troublesome or hazardous, yet as it is always possible to become so, and that very suddenly, it can never be prudent or safe to neglect it.

"Even though the rupture should be of the omental kind (which considered abstractedly is not subject to that degree or kind of danger to which the intestinal is liable) yet it may be secondarily, or by accident, the cause of all the same mischief; for while it keeps the mouth of the hernial sac open, it renders the descent of a piece of intestine always possible, and consequently always likely to produce the mischief which may proceed from thence.

"They who labour under a hernia thus circumstanced, that is, whose ruptures have been generally down while they have been in an erect posture, and which have either gone up of themselves, or have been easily put up in a supine one, should be particularly careful to have their truss well made, and properly fitted for the mouth of the sac; and the opening in the tendon being both large and lax, and the parts having been used to descend through it, if the pad of the truss be not placed right, and there be not a due degree of elasticity in the spring, a piece of intestine will, in some posture, slip down behind it, and render the truss productive of that very kind of mischief which it ought to prevent."—(See *Truss*.)

[This accident, so justly deprecated by Mr. Pott, is not only frequent, but unavoidably so, if the rupture pad of the truss be "fitted for the mouth of the sac," as he directs in this paragraph. For if the internal surface of the pad be *convex*, as was formerly universal, and thought indispensable and as indeed Mr Pott

plainly intimates; it is no marvel that a "piece of intestine should slip down behind it," because the pad is "fitted *for* the mouth of the sac," and the "opening in the tendon" is thereby made larger and more lax by the instrument itself, and the liability increased to a recurrence of the accident.

If on the contrary the rupture pad be *concave* on its internal surface, and thus by its raised circular margin fitted to *close* the mouth of the sac, instead of opening it as it does when convex, this accident, so inconvenient and so often fatal, could not happen. This is an *American* improvement; but this is not a sufficient reason for its being passed over in silence by Dr. Cooper. See note on the article Truss.—*Reese.*]

Mr. Pott then comments upon the importance of having the parts completely reduced before the truss is applied, and upon the danger that may be incurred by laying such bandage aside after it has been worn some time; since the partial closure of the ring, whereby the descent of the gut is rendered less easy, will also make the reduction more difficult, if a piece should happen to slip down: and hence he insists, that a truss "should be long and unremittingly worn by all those whose time of life makes the expectations of a perfect cure reasonable, many of the ruptures of adults being owing to the negligent manner in which children at school are suffered to wear their trusses."

Besides the danger of strangulation, and the loss of all chances of a radical cure, when a reducible hernia is neglected, and allowed to remain down, there are other motives for keeping up the tumour with a truss, and preventing its increase of size. The vast size to which neglected herniæ sometimes increase, not only prohibits all active exertion, but, by involving, in the male, the integuments of the penis, incapacitates the subject from the act of copulation, and gives rise to excoriation from the discharge of the urine over the swelling. Probably, too, the testis may be affected by the pressure of a very large scrotal hernia.—(*Morgagni de Caus. et Sed. ep.* 33, *art.* 12; *Schmucker, Vermischte Chir. Schriften, b.* 3, *p.* 195.) Disorders of the intestinal functions invariably attend these large ruptures, and increase in frequency and violence in proportion to the size of the swelling, and age of the patient. All the moveable viscera of the abdomen gradually find their way into the hernial sac, if a rupture be entirely neglected.—(*Lawrence on Ruptures, p.* 80, *edit.* 4.)

TREATMENT OF IRREDUCIBLE HERNIÆ, FREE FROM INFLAMMATION, AND UNATTENDED WITH TROUBLESOME OR DANGEROUS SYMPTOMS.

Mr. Pott, and all the best writers on ruptures, ascribe the incapacity of reduction, in most cases, either to the largeness of the quantity of the contents, an alteration made in their form and texture, or to adhesions, which they have contracted with each other or their containing bag. The reduction is also sometimes prevented by transverse membranous bands within the sac.

Mr. Pott was also aware that ruptures are sometimes rendered difficult to be reduced, by the cœcum being contained in the hernial sac. Of this fact he was as much convinced, as the nature of such kind of things would permit; that is, by observations made both on the living and the dead. This statement, made by Pott many years back, deserves particular notice, because its truth is confirmed by the modern observations of Scarpa, whose very important explanations of the cause of the difficulty of reduction, may be seen in the last edition of the *First Lines of Surgery.*

Mr. Pott has adverted to the kind of impediment to reduction produced by the thickening of the neck of the sac, when the hernia is long neglected, and suffered to remain in the scrotum without any bandage to support its weight.

The same author reckons an alteration produced by time, and constant though gentle pressure, in the form and consistence, or texture of the omentum, as no infrequent cause why neglected omental ruptures become irreducible.

When a portion of omentum "has been suffered to remain for a great length of time in the scrotum, without having ever been returned into the belly, it often happens, that although that part of it which is in the lower part of the hernial sac preserves its natural, soft, adipose, expansile state, yet all that part which passes through what is called the neck of the sac is, by constant pressure, formed into a hard, firm, incompressible, carnous kind of body, incapable of being expanded, and taking the form of the passage in which it is confined, exactly filling that passage, and rendering it impossible to push up the loose part which fills the scrotum.

"The same reason for incapacity of reduction is also sometimes met with in ruptures of the intestinal kind, from an alteration produced on that part of the mesentery which has been suffered to lie quiet for a great length of time in the neck of an old hernial sac.

"The other impediment, which I mentioned, to the return of old ruptures, is the connexion and adhesion of the parts, either with each other, or with the bag containing them. This is common to both the intestinal and omental hernia, and is produced by slight inflammations of the parts, which have been permitted to lie long in contact with each other, or perhaps in many cases from the mere contact only. These adhesions are more or less firm in different cases, but even the slightest will almost always be found an invincible objection to the reduction of the adherent parts, by the hand only.

"Many, or perhaps most, of these irreducible ruptures, become so by mere time and neglect, and might at first have been returned: but when they are got into this state, they are capable of no relief from surgery but the application of a suspensory bag, to take off, or lessen the inconvenience arising from the weight of the scrotum.

"People in this situation should be particularly careful not to make any attempts beyond their strength, nor aim at feats of agility; they should take care to suspend the loaded scrotum, and to keep it out of the way of all harm from pressure, bruise, &c. When the tumour is very large, a soft quilted bolster should be worn a the bottom of the suspensory to prevent excoriation, and the scrotum should be frequently washed for the same reason; a loss of skin in this part, and in such circumstances, being sometimes of the utmost importance. They ought also to be particularly attentive to the office of the intestinal canal, to see that they do not by any irregularity of diet disorder it, and keep themselves from being costive." Mr. Pott observes, however, that the quiet, inoffensive state of this kind of hernia is by no means to be depended upon: many things may happen to it by which it may be so altered, as to become hazardous, and even fatal: an inflammation of that part of the gut which is down, any obstruction to the passage of the aliment or fæces through it, a stricture made by the abdominal tendon, either on what has been long down, or on a new portion which may at any time be added to it, are always capable of so altering the state of the case, as to put the life of th patient into danger.

"Indeed, the hazard arising from a stricture made on a piece of intestine contained in the sac of an old irreducible hernia, is in one respect greater, than that attending one that has been found at times reducible; since from the nature of the case it will hardly admit of any attempt towards relief, but the operation, which in these circumstances must necessarily be accompanied with additional difficulty.

"Among the ruptures which have been thought not reducible, and treated as such, there have been some which, upon more judicious and more patient attempts, have been found capable of reduction.

"When this is suspected to be the case, the proper method is by absolute rest, in a supine posture for a considerable length of time, by great abstinence, and the use of evacuants, so as to lessen the size of the parts in the hernial sac, and render them capable of passing back again into the belly."—(*Pott on Ruptures.*)

Fabricius Hildanus gives an account of a man, who was radically cured of a rupture, of twenty years' date, by six months' confinement to bed.—(*Cent.* 5, *obs.* 54.)

Le Dran and Arnaud relate instances of monstrous bubonoceles, which disappeared entirely, after the patients had been long confined to bed, and rendered much emaciated by tedious illnesses. Some of the moderns have imitated this operation of nature, and by frequent bleedings, and repeated purges, have sometimes so far reduced the size of the hernia, that it has been returned into the abdomen. Mr. Hey has several times succeeded in this way.—(*P.* 219.) But, the practice cannot prove successful, when the viscera adhere to the sac, or to the peritoneum, just within the abdomen. The greatest objection to this method of cure is the want of an absolute criterion for distinguishing

when the parts do or do not adhere to the hernial sac; and, in advanced years, though one were sure that the viscera were free from the sac, the possibility of hurting the body, by the necessary evacuations, is also another objection.—(*Sharp's Critical Inquiry, p.* 15.)

Were the plan to be thought worthy of trial, keeping up a constant pressure on the tumour, by means of a suspensory bandage, made to lace in front, would be proper for promoting the absorption of the thickened parts in the hernial sac. Sir A. Cooper has reduced such hernia, after applying ice to them; the good effects of which he imputes to its producing a contraction of the scrotum, and thus a strong and permanent compression of the tumour. Mr. Earle once mentioned to me the suggestion of keeping up a general pressure on the swelling, by means of a bladder containing quicksilver, the quantity of which can be regulated according to circumstances.

Whenever any attempts of this kind succeed, a truss should be immediately put on, and worn without remission.

However, there are instances on record where the capacity of the abdomen had become so adapted to the diminished quantity of the viscera, that when the contents of the hernia were reduced, serious complaints arose from their introduction into the belly. Schmucker met with several such cases, in which he was obliged to take off the truss again. Petit has known the reduction of a hernia of this kind prove fatal, the parts not descending again when the truss was removed, the nausea and vomiting continuing, and peritonitis taking place.—(*Chirurgische Wahrnehmungen, vol.* 2, *p.* 243. *Maladies Chir. t.* 2, *p.* 392.)

Mr. Pott remarks, that "an omental rupture, which has been so long in the scrotum as to have become irreducible, is very seldom attended with any bad symptoms, considered abstractedly; but it is constantly capable of being the occasion of an intestinal hernia, and all its consequences: neither is that all; for the omentum, either so altered in form and texture, or so connected as to be incapable of reduction, may by accident inflame, and either become gangrenous, or suppurate, and the occasion of a great deal of trouble." In a few instances, epiploceles produce very bad symptoms indeed, cases of which are to be found in Garengeot, Dionis, &c.

Sometimes, in old cases of entero-epiplocele, the intestine is reducible, but the omentum is not; in which case some writers advise keeping up the piece of bowel with a truss, the pad of which must be so contrived as not to press on the omentum. Mr. Pott, however, considers this method not often practicable, and, should such a truss be used, he recommends great caution in its construction and application, lest a small piece of gut slip down, and, being pressed on by the truss, produce fatal mischief.

"Irreducible herniæ must of course be exposed to all the consequences of external injury and violence; hence, various cases are recorded in which the bowels have been burst by blows, falls, &c."—(*Lawrence on Ruptures, p.* 131, *edit.* 4.)

For examples of such accidents, Mr. Lawrence refers to *A. Cooper on Hernia, part* 2, *Pref. p.* 2; *and to Travers's Inq. into the Process of Nature, &c. p.* 37. A case is also quoted from Scarpa, *p.* 310, where a violent exertion caused a sudden return of a hernia which had been long regarded as cured. The viscera lay in the tunica vaginalis, which was burst to the extent of an inch.

SYMPTOMS AND TREATMENT OF A STRANGULATED, OR AN INCARCERATED HERNIA.—MEANS TO BE TRIED BEFORE AN OPERATION.

"Difficulty of reduction (says Pott) may be owing to several causes. The size of the piece of omentum, or the inflamed state of it; the quantity of intestine and mesentery; an inflammation of the gut, or its distention by feces or wind; or the smallness of the aperture of the tendon through which the hernia passes. But, to whatever cause it be owing, if the prolapsed body cannot be immediately replaced, and the patient suffers pain, or is prevented thereby from going to stool, it is called *an incarcerated hernia, a strangulated hernia,* or *a hernia with stricture.*

"The symptoms are a swelling in the groin or scrotum, resisting the impression of the fingers: if the hernia be of the intestinal kind, it is generally painful to the touch, and the pain is increased by coughing, sneezing, or standing upright. These are the very first symptoms, and, if they are not relieved, are soon followed by others, viz. a sickness at the stomach, a frequent retching or inclination to vomit, a stoppage of all discharge per anum, attended with a frequent hard pulse and some degree of fever."

A patient thus circumstanced is in some danger, and demands immediate assistance. A stricture made on the prolapsed part of the gut by the aperture through which it passes, is the immediate cause of all the bad symptoms, and of course the removal of such stricture is the only thing which can bring relief. This object can only be accomplished by returning the bowel back into the abdomen, or dividing the parts which form the stricture. The former plan is always the most desirable, when practicable.

We next proceed to notice the various measures to be adopted for the relief of a strangulated hernia, so as to obtain the best chance of doing away the necessity of an operation. After treating of the merits of each plan, a few remarks will be offered on the order in which the means should be put in practice.

Taxis.—This is the term applied to the operation of reducing a hernia with the hand. It is much promoted by the position of the body; which Winslow thought should be placed on an inclined plane and the thighs bent towards the trunk. Sir A. Cooper advises the same practice, observing that this posture by relaxing the fascia of the thigh, relaxes also the aperture through which the hernia passes. Every degree of tension and relaxation of the femoral fascia, must undoubtedly be attended with a corresponding change in the abdominal ring. But flexion of the thigh, besides relaxing this fascia, also relaxes the abdominal internal iliac, and psoas muscles. In cases of inguinal hernia, the pressure made on the tumour by the hands of the surgeon, should always be directed upwards and outwards, along the course of the spermatic cord; and Sir A. Cooper advises it to be continued from a quarter to half an hour.—(*On Inguinal and Congenital hernia.*)

As the femoral hernia passes downwards and then forwards, the pressure must be directed first backwards and then upwards. In umbilical and ventral herniæ it is to be made straight backwards. No violence should ever be used; for, besides being unavailing, it greatly aggravates the inflamed state of the contents of the hernial sac, and has been known even to burst the intestine.—(See *Cooper on Inguinal Hernia, &c. p.* 23.)

Besides bending the thigh, care should also be taken to rotate it inwards, which will have great effect in relaxing the femoral fascia and tendon of the external oblique muscle. Suspension of the patient over the shoulders of an assistant has been thought to facilitate reduction: "I have tried it often (says Mr. Hey), but have not found it to be of such superior efficacy as some authors have represented."—(*P.* 144.)

The manœuvre of gently pulling the intestine downwards, or a little way further out of the ring, previously to the attempt to reduce the hernia, has been suggested. —(See *Balfour's New Mode of the Taxis, in Med. and Phys. Journ. Nov.* 1824.) The plan, I believe, is not entirely new, and it is noticed by Mr. Lawrence; who says, that it will sometimes succeed, when the difficulty of reduction is owing to an accumulation of fecal matter.

The return of a piece of intestine is generally preceded by a peculiar noise, caused by the passage of air through the stricture. It recedes at first gradually, and then slips up suddenly. The omentum goes up slowly to the very last portion, which must be actually pushed through the opening. If the taxis should not succeed at first, it will often do so after the warm bath, bleeding, or cold applications. Small herniæ, being attended with the closest stricture, are the most difficult to reduce, and, for the same reason, crural ruptures do not so often yield to the taxis, as inguinal herniæ in the male subject. The taxis becomes less likely to succeed, the longer the inflamed viscera have been down, because adhesions are liable to form. Mr. Lawrence observes (*p.* 63,) "When the rupture becomes painful, we are no longer justified in persevering in attempts at reduction by the hand. A sufficient pressure cannot now be endured; and the force which is employed only tends to increase the inflammation, and accelerate the approach of gangrene. *At this period, the operation is required, and should be performed without*

delay." Desault even proscribed the taxis altogether in the inflammatory strangulation, until the previous use of other means had produced a change in the state of the swelling.

That the taxis is frequently abused, and the cause of serious mischief, is a truth which cannot be doubted. "Strangulated herniæ (says Scarpa) very frequently mortify from the negligence of the patients, and their repugnance to submit to an operation; and, perhaps, still more frequently from the effect of the taxis, unskilfully exercised by uninformed surgeons, who are determined, at any price whatsoever, to accomplish the speedy reduction of the viscera. The majority of them make no distinction between the *acute* and the *chronic* strangulation. In both cases, no sooner are the symptoms of strangulation evinced, than they begin to handle the swelling roughly, and to push the viscera with all their force, in order to make them return into the abdomen; while, when the strangulation is *acute*, and the patient young and strong, the taxis ought never to be practised, before all the means proper for diminishing the strength, calming spasm, and relaxing the parts, which are to be reduced, have been employed for a certain time. These means, we know, are bleedings, fomentations, emollient clysters, and especially the warm bath, which, next to bleeding, holds the first rank. At this school of surgery, I have frequently had opportunities of observing the salutary effect of this treatment. My pupils have, more than once, seen herniæ, which had been painfully handled, without any good, reduced, as it were, spontaneously, after a bleeding, or while the patient was in the bath. If what I have said upon the subject of the *acute* strangulation, and the treatment that it requires, were generally known by surgeons, I think that operations for strangulated herniæ would be less frequent."

[The distinction here made by Scarpa is one of the greatest practical importance, and one which no surgeon should lose sight of in his attempts at the taxis. The terms *acute* and *chronic* applied to each individual case of incarcerated hernia, will be intelligible to the merest tyro, although the ambiguity in the application of these terms to other subjects is too obvious and perplexing to be denied. To recognise this distinction will result as Mr. Scarpa predicts, and operations for strangulated hernia will be less frequent, "and the taxis will very generally be successful." I speak on this subject from a personal knowledge of its value; and for several years, although sent for frequently to operate, I have been able to succeed in dispensing with the use of the knife very generally, by a modification of the practice here recommended, after the taxis had been ineffectually attempted for hours, and in one instance these attempts had been continued at intervals for two days.—*Reese.*]

"Things are different with regard to the *chronic* strangulation of old large herniæ, in feeble or aged persons; for, in these cases, it is of great importance to support the patient's strength. Bleeding, the warm bath, and other weakening means should also be avoided, which, in producing a general atony, might bring on gangrene of the intestine, either during the strangulation, or after the reduction of the viscera. It is ascertained, that these kinds of strangulation are almost always occasioned by an accumulation of fecal matter, or an extraordinary quantity of air in the hernia. Nothing is more efficacious than cold applications, for promoting the action of the bowel on the matter, which distends it, or for lessening the volume of the air. They produce a corrugation of all the scrotum, and contractions of the cremaster, which alone sometimes suffice for reducing the viscera, in a much better manner than could be done by the hands of the most experienced surgeon."—(*Scarpa, Traité des Hernes, p.* 244—247.)

Bleeding.—The inflammation which attacks the protruded viscera, and spreads thence over the whole abdomen, and the temporary weakness and often fainting, which the sudden loss of blood induces, and which is a peculiarly favourable opportunity for reducing the hernia by the hand, are the reasons in favour of bleeding. Sharp, Pott, B. Bell Sabatier, Richter, Callisen, and Scarpa, names which can never be surpassed in respectability, are all in favour of bleeding. Wilmer, Alanson, and Sir Astley Cooper have published against the practice. Mr. Hey has related two cases, which strongly evince the manner in which bleeding facilitates the return of a hernia; the protruded viscera, in one instance, went up spontaneously, on blood being taken away; in the other, the taxis succeeded immediately afterward, though the previous attempt had been made in vain.—(*P.* 125, 126.) Mr. Hey's experience, however, leads him to concur so far with Wilmer and Alanson, as to declare, that bleeding has generally failed to procure a reduction of the strangulated intestine, though he is persuaded that, in many cases, it may be used with advantage. But he cannot agree with Wilmer, that it generally renders the subsequent operation more dangerous.—(*P.* 126.) The majority of candid practitioners, I believe, will allow, that bleeding is always proper, when the hernia is small and recent, the abdomen tense and painful, and the patient young, strong, and plethoric.

Purgative Medicines.—My experience (says Mr. Hey) leads me to condemn almost universally the use of purgatives, while an intestine remains firmly strangulated. In the entero-epiplocele, when the intestine has retired, and the omentum remains strangulated; or in a simple strangulation of the omentum, where the intestine has not been prolapsed; purgatives are of great utility. So likewise in very large and old herniæ, where there is reason to doubt, whether the disease is not to be considered as a morbid affection of the intestinal canal, rather than the effect of strangulation, purgatives may be as useful as in the simple ileus without hernia. While the intestine remains firmly strangulated, they usually increase the vomiting, and add to the distress of the patient. If they are to be tried at any time with hope of success, the trial would appear to have the greatest advantage when the vomiting has been removed by means of an opiate; yet I have repeatedly given them in vain during such an interval of relief.—(*Practical Obs. in Surgery, p.* 128.)

Purgatives are supposed to operate by exciting the peristaltic action of the intestine, and thereby extricating it from the stricture. Besides the above eminent surgeon, Pott and Richter have joined in their general condemnation, and, to all appearances, with very great reason. Purgative clysters certainly have not the objection of increasing the irritation; but their efficacy is not deserving of much confidence. Mr. Hey never saw one case, in which either purgative, or emollient clysters produced a return of a strangulated hernia. Such injections will empty the large intestines; but they do no more. It is common also for a natural evacuation to be the immediate consequence of strangulation.—(*P.* 131.)

Warm Bath.—"Many instances (says Hey) are upon record of the good effect of warm bathing in procuring the reduction of a strangulated hernia. I have often seen it useful; but I have often seen it fail. Whenever it is used in this disease, the patient should be placed, if possible, in a horizontal position. Gentle efforts with the hand to reduce the prolapsed part are perhaps attended with less danger, and greater prospect of success, while the patient lies in the bath, than in any other position. The free use of opiates coincides with that of warm bathing, and, under some circumstances, these means deserve to be tried in conjunction."—(*P.* 132.)

Cold Bath, and Cold Applications.—The cold bath, and dashing of cold water on the patient, are little to be depended on, though success has sometimes been obtained in this manner.—(*Petit, Traité des Chir. t.* 2, *p.* 325; *Hey, p.* 136.)

Wilmer strongly recommended the application of cold to the tumour itself, and this plan has acquired the approbation of the most celebrated modern surgeons. It is generally tried in conjunction with the effect of tobacco clysters, which will be presently noticed. Cold applications, in the form of ice, were indeed particularly recommended by B. Bell. The best way is to pound the ice, tie it up in a bladder, and place it on the rupture. When ice cannot be procured, Sir A. Cooper employs a mixture of equal parts of nitre and muriate of ammonia. To one pint of water, in a bladder, ten ounces of the mixed salts are to be added. "If, after four hours, (says this distinguished surgeon) the symptoms become mitigated, and the tumour lessens, this remedy may be persevered in for some time longer; but if they continue with unabated violence, and the tumour resist every attempt at reduction, no farther trial should be made of the application."—(*On Inguinal and Congenital Hernia.*) When ice is not at hand, either some

times proves a good substitute, when allowed to evaporate from the surface of the swelling.

Care must be taken that the cold be not so applied as to freeze the scrotum, and bring on sloughing.—(*A. Cooper*, *p.* 15.)

[The importance of cold applications to the hernial tumour cannot be too strongly urged upon the practitioner; and hence this caution of Sir A. Cooper in the use of ice, lest "sloughing be produced by freezing the scrotum," may intimidate some younger practitioners from persevering in the practice sufficiently long. That the long-continued application of ice, and some frigorific mixtures still colder, (or to speak more "secundum artem," producing a still greater absorption of caloric,) may do mischief in this way, cannot be questioned.

But the substitute for ice, proposed by Mr. Cooper when this is not to be had, will be found preferable to the ice itself, particularly as its stimulating effects upon the surface remove all liability to freezing the parts. If the "Æther Sulphuricus" of the shops, highly concentrated, be poured upon the tumour at short intervals, and its evaporation be promoted by the brisk use of the bellows, a more speedy effect will be produced than by the ice. or combination of salts.—*Reese.*]

Opiates.—Mr. Hey met with several cases, in which opiates, given freely (in athletic persons after bleeding), procured a reduction of strangulated hernia.

He cannot say, however, that this remedy is generally successful; but it has the advantage of removing, for a time, the pain and vomiting usually attendant on strangulation, even though it prove ultimately inefficacious. Opiates should be given in large doses, when it is wished to try their effect in procuring reduction; and whenever the symptoms of strangulation return, after having been removed by opiates, the operation should be performed without delay.—(*P.* 134, 135.)

Tobacco Clysters.—For this purpose, some surgeons prefer a decoction of tobacco, made by infusing, or boiling, one drachm of the plant, for ten minutes, in a pint of water; others employ the smoke, which is prepared, and introduced into the rectum, by means of an apparatus sold at almost every surgical instrument-maker's. Perhaps both methods are equally efficacious; but, as one requires an apparatus, while the other does not, and is equally proper, the decoction may be entitled to most recommendation. The machine for the smoke is also frequently out of order. Next to the operation, tobacco clysters are the most certain means of bringing about the reduction of the strangulated parts. Besides exciting the action of the intestines, they exert a peculiarly depressing influence on the whole system, reducing the pulse, and causing nausea and sickness, cold sweats and fainting, under which circumstances, the parts often recede spontaneously, or may be easily reduced. Sir A. Cooper prudently advises injecting half the above quantity at first; for he has seen two drachms, and even one, when used as an infusion, and introduced at once, prove fatal.—(*P.* 24.) The rest should be injected presently, when it appears that the tobacco does not operate with the extraordinary violence with which it does in a few particular constitutions.

A case, published by Mr. C. Bell, looks to me very much like an example of the occasional poisonous effects of the tobacco, though not reported as such by the author. At least no particulars of any fatal mischief, either in the tumour or abdomen, are detailed; and it is remarked of the patient, "His strength held up until the tobacco clyster was administered to him, after which, he very suddenly fell low, and sunk."—(*Surgical Obs. part* 2, *p.* 189.) The smoke proved fatal in an instance witnessed by Desault (*Œuvres de Chir. t.* 2, *p.* 344); and an infusion of ℥ ij. to ℥ viij. of water seemed to produce suddenly mortal effects in another example on record.—(*Edinb. Med. and Surgical Journ. vol.* 9, *p.* 159.)

[I have often seen the most threatening symptoms produced by the injection of the tobacco; and lest some should shrink from the use of this violent remedy where it would be expedient to employ it, I would here state, as the result of my experience and observation, that in several instances where the most alarming symptoms supervened after the use of tobacco, I have found an injection per anum of an ounce of oleum terebinthina has suddenly removed the symptoms, and roused the patient from the syncope. I remember one case in which the hernia was reduced *sud sponte* by the tobacco clyster; the nausea, cold sweats, and fainting which followed threatened instant dissolution, but by the prompt enema of terebinthina, which was in readiness, a free evacuation of the bowels was produced, and the patient very speedily recovered. Whether there is any antidotal property, by the incompatibility of the two agents, may not be easily deduced; but the effects I have often seen when the tobacco has been premised in the treatment of obstipatio.—*Reese.*]

Poultices and Fomentations have not the confidence of any experienced or intelligent surgeon. Whoever, in these urgent cases, wastes time, in trying the effects of such applications, merits censure for his credulity, ignorance, and unfitness to undertake the treatment of a rapid disease, in which, as Pott remarks, if we do not get forward, we generally go backward; and whatever does no good, if it be at all depended upon, certainly does harm, by occasioning an irretrievable loss of time.

OF THE ORDER IN WHICH THE PRECEDING METHODS SHOULD BE TRIED, AND OF THE TIME WHEN THE OPERATION SHOULD NOT BE DELAYED.

In the treatment of a strangulated hernia, a surgeon cannot be too deeply impressed with the danger of spending time in the trial of methods of inferior efficacy, or of such as are evinced to be ineffectual in the cases before them.

The rapidity with which gangrenous mischief sometimes arises, and the patient loses his life, has been proved in a multitude of unfortunate examples, and should operate as a warning to all practitioners against the danger of deferring the operation too long. In the course of my reading, however, I have not met with so remarkable an instance of the sudden mortification and rapidly fatal termination of a hernia, as the following case recorded by Baron Larrey, in speaking of the fatiguing and forced marches performed by the French soldiers in Egypt. These marches, he says, brought on, in one case, "a hernia, which formed suddenly, and became at the same time strangulated. The man was immediately brought to my ambulance; but a spontaneous gangrene, which had all on a sudden attacked the intestine, and extended to the other abdominal viscera, caused the patient's death in the space of two hours, and made it impossible for me to do the operation for him. This is the second example, that I have been acquainted with, in which the effects were thus rapid."—(*Mém. de Chir. Militaire*, *t.* 1, *p.* 196.)

The taxis is generally among the first things to be tried, and Sir A. Cooper thinks the attempts should be continued for a quarter, or half an hour. When these have been ineffectual, the patient, if the circumstances do not forbid, should be immediately bled, and have a large opening made in the vein, so that the suddenness of the evacuation may be most likely to bring on fainting. The taxis should then be tried again.

When the strangulation is very *acute*, and the patient young and strong, perhaps it may be most advisable to follow the advice delivered by Scarpa and Desault, which is to bleed the patient, and put him in the warm bath, before the taxis is attempted at all.

If bleeding alone has been practised, and the manual efforts at reduction should not now succeed, the warm bath may be employed, *provided it can be got ready in a very short time*, but none should ever be lost in waiting for it to be prepared. When the bath is used, the taxis may be attempted, as the patient lies in the water; a situation in which I have succeeded in reducing several herniæ.

Certainly not more than one hour should ever be allotted for putting in practice the first attempts at reduction, bleeding, and the warm bath.

The plan should be, while the trial of one thing is going on, another should be preparing; so when the preceding measures have been tried in vain, the application of a bladder filled with ice, or the solution of nitre and muriate of ammonia, and the injection of tobacco, in the form of smoke, or decoction, should never be delayed for want of due previous preparation of all the requisites. Both these measures should be practised at the same time, immediately after the failure of the taxis, bleeding, and the warm bath. Sir A. Cooper computes, that four hours are enough for the trial of the tobacco clyster, together with cold applications.

In omental herniæ, the necessity for operating may

frequently be obviated, by the good effects of bleeding, purgative medicines, and clysters, and leeches applied to the tumour. Mr. Lawrence has justly observed, that "when, as it very frequently happens, the aid of the surgeon is not required, until the complaint has lasted for some time, a trial of the tobacco, together with the topical use of cold, should be immediately resorted to, as circumstances will not admit of delay in the previous use of less powerful remedies."—(*P.* 148, *edit.* 3.)

Every man who has seen much of herniæ, will immediately recognise the propriety of the following sentiments of the experienced Mr. Hey.

"I can scarcely press in too strong terms the necessity of an early recourse to the operation, as the most effectual method of preserving life in this dangerous disease. If Mr. Pott's opinion be true, that the operation, when performed in a proper manner, and in due time, does not prove the cause of death oftener than perhaps once in fifty times; it would undoubtedly preserve the lives of many, to perform it almost as soon as the disease commenced, without increasing the danger by spending much time in the use of means which cannot be depended upon for a cure.

"I have twice seen this disease prove fatal in about twenty-four hours. In such cases, it is evident there is little time for delay. A surgeon, who is competent to perform the operation, is not perhaps consulted till the intestine is on the point of being mortified, or is actually in a state of mortification. The dilemma into which he is then cast, is painful indeed. But when the fullest opportunity is afforded him of using the best mode of treatment, I am satisfied that his success will be the greatest when the operation is not long delayed. This, at least, has been my own experience. When I first entered upon the profession of surgery in the year 1759, the operation for the strangulated hernia had not been performed by any of the surgeons in Leeds. My seniors in the profession were very kind in affording me their assistance, or calling me into consultation when such cases occurred; but we considered the operation as the last resource, and as improper until the danger appeared imminent. By this dilatory mode of practice, I lost three patients in five, upon whom the operation was performed. Having more experience of the urgency of the disease, I made it my custom, when called to a patient who had laboured two or three days under the disease, to wait only about two hours, that I might try the effect of bleeding (if this evacuation was not forbidden by some peculiar circumstances of the case) and the tobacco clyster. In this mode of practice, I lost about two patients in nine, upon whom I operated. This comparison is drawn from cases nearly similar, leaving out of the account those cases in which a gangrene of the intestine had taken place.

"I have now, at the time of writing this, performed the operation thirty-five times; and have often had occasion to lament, that I had performed it too late, but never that I had performed it too soon. There are some cases so urgent, that it is not advisable to lose any time in the trial of means to produce a reduction. The delay of a few hours may cut off all hope of success, when a speedy operation might have saved the life of the patient."—(*P.* 141, *&c.*)

To determine the exact moment, when to give up the trial of the preceding measures, and to have immediate recourse to the operation, is certainly difficult; but, no one can doubt, that it is generally better to operate too early, than too late.

All directions must be general ones, liable to many exceptions: in rapid cases, little or no time should be allotted to the trial of any plan, and the operation should be done without the least delay. In other instances, we have full time to try the effects of every thing at all likely to succeed. The symptoms, which ought to guide us, in having recourse to the operation, arise from an attack of inflammation in that part of the intestine contained in the hernial sac, and from its spreading into the abdominal cavity. It is in proportion to their violence, that we ought to urge the performance of the operation. Sir A. Cooper considers pain on pressing the belly, and tension, as the symptoms which point out its immediate necessity. He adds, "indeed, there is scarcely any period of the symptoms, which should forbid the operation; for, even if mortification has actually begun, the operation may be the means of saving life, by promoting the ready separation of gangrenous parts"—(*On Inguinal and Congenital Hernia, p.* 27.)

Whenever the surgeon has succeeded in reducing the parts, without having recourse to the knife, if the symptoms of pain, inflammation, &c., ran high before such reduction, they will not always cease immediately afterward. As they probably depend on the reduced bowel having been inflamed by the stricture, the body should be kept open, and the diet and regimen should be low and sparing, while the least degree of pain and tension remain; in short, till all complaint is absolutely removed from the abdomen, and the intestines do their office freely, and without trouble.—(*Pott.*)

PROGRESS OF THE SYMPTOMS OF A STRANGULATED HERNIA.

The earliest symptoms have been already related, viz. "tumour in the groin or scrotum, attended with pain, not only in the part, but all over the belly, and creating a sickness and inclination to vomit, suppression of stools, and some degree of fever. These are the first symptoms, and, if they are not appeased by the return of the intestine; that is, if the attempts made for this purpose do not succeed; the sickness becomes more troublesome, the vomiting more frequent, the pain more intense, the tension of the belly greater, the fever higher, and a general restlessness comes on, which is very terrible to bear When this is the state of the patient, no time is to be lost; a very little delay is now of the utmost consequence; and if the one single remedy which the disease is now capable of, be not administered immediately, it will generally baffle every other attempt. This remedy is the operation, whereby the parts engaged in the stricture may be set free. If this be not now performed, the vomiting is soon exchanged for a convulsive hiccough, and a frequent gulping up of bilious matter: the tension of the belly, the restlessness, and fever having been considerably increased for a few hours, the patient suddenly becomes perfectly easy, the belly subsides, the pulse, from having been hard, full, and frequent, becomes low, languid, and generally interrupted, and the skin, especially that of the limbs, cold and moist: the eyes have now a languor and a glassiness, a lack-lustre not easily to be described; the tumour of the part disappears, and the skin covering it sometimes changes its natural colour for a livid hue; but whether it keeps or loses its colour, it has an emphysematous feel, a crepitus to the touch, which will easily be conceived by all who have attended to it, but is not so easy to convey an idea of by words: this crepitus is the too sure indicator of gangrenous mischief within. In this state, the gut either goes up spontaneously, or is returned with the smallest degree of pressure; a discharge is made by stool, and the patient is generally much pleased at the ease he finds; but this pleasure is of short duration, for the hiccough and the cold sweats continuing and increasing, with the addition of spasmodic rigours and subsultus tendinum, the tragedy soon finishes."—(*Pott.*)

According to Sir Astley Cooper, one of the earliest symptoms of a strangulated hernia is pain about the diaphragm, followed by continual eructation. The patient is next troubled with vomiting and costiveness. He feels a great inclination to have stools, but cannot succeed in his attempts to expel the feces. There is some pain in the swelling; and a great deal at the part where the stricture is situated. Afterward the abdomen becomes considerably distended with air, such distention not arising at first from inflammation, but from the cause here mentioned, as is proved by pressure on the abdomen not giving at first any pain. The vomiting becomes more frequent, and feculent matter is ejected from the stomach; into which it is brought by what is called the antiperistaltic action of the bowels. A clyster will sometimes bring away a portion of feculent matter, but the quantity will be extremely small. While the abdomen is in this tense state, but unaccompanied with pain, and while there is frequent vomiting of the feces, the pulse is hard, frequent, and very distinct; but, in the next stage of the symptoms, when the abdomen is not only tense, but painful on being touched, the pulse is extremely small and frequent. The vomiting and eructation continue, and the patient is pale, and covered with a cold perspiration. The tumour becomes very tense, hard, and in general a little inflamed on the surface of the skin

With respect to the hiccough which now succeeds, and which has usually been considered as a sign of the presence of gangrene, Sir Astley Cooper declares, that it is now known not to be so, patients having had it for many hours, and yet recovered after the operation. Hiccough sometimes continues several days, after the latter proceeding, and, in this case, bleeding does more good than any other measure.—(See *Lancet*, *vol.* 2, 120.)

ANATOMY OF INGUINAL HERNIA.

This subject must necessarily precede the account of the operation, which would otherwise be unintelligible. It is chiefly in the anatomical information relative to hernia, and in the mode of operating, that modern surgeons have a decided superiority over their predecessors; for, before Gimbernat, Camper, Hey, Lawrence, Cooper, Scarpa, Hesselbach, Langenbeck, and Cloquet published their several works on hernia, the anatomy of the disease was but imperfectly understood.

The tendinous fibres of the aponeurosis of the external oblique muscle, as they run downwards and forwards towards the pubes, separate from each other so as to leave a triangular opening, called the abdominal ring, which is usually more capacious in the male than the female subject. The upper and inner pillar (as it is termed) of this aperture is inserted into the symphysis of the pubes, and is the weakest of the two; the lower and outer one, which is the strongest, is chiefly a continuation of Poupart's ligament (*Hesselbach, über den Ursprung, &c. der Leisten-und-Schenkelbrüche*, *p.* 4), and is fixed into the angle and crista of the same bone. Some tendinous fibres cross the upper and outer angle of the ring, so as to diminish the triangular appearance of the whole aperture: these are said to be very strong in old herniæ. The anterior and thicker layer of the aponeurosis of the internal oblique muscle joins the tendon of the external oblique; the posterior and thinner one joins that of the transversalis; but the lower portion of this tendon, together with the corresponding part of the transversalis, goes wholly in front of the rectus muscle. Thus, the inferior border of the obliquus internus and transversalis, which originates from the upper part of Poupart's ligament, lies behind the outer pillar of the abdominal ring. Sir A. Cooper first noticed, that a thin fascia proceeds from the inner edge of Poupart's ligament, and spreads over the posterior surface of the transversalis. This fascia forms the only partition between the peritoneum and the outer opening of the abdominal ring, and were it not for its existence, inguinal herniæ would probably be much more frequent. The partition in question, however, is said by Scarpa to be formed by the aponeurosis of the internal oblique and transverse muscles; while Hesselbach, who has named the small smooth point, situated directly behind the outer opening of the abdominal ring, its *crural surface*, distinctly states, that it is formed by delicate fleshy and tendinous fibres of the internal oblique muscle (*Ueber den Ursprung, &c. der Leisten-und-Schenkelbrüche*, *p.* 4); and that behind them is the weakest part of what he names the *internal inguinal ligament*, in the rear of which is the peritoneum, with the intervention of a very loose cellular substance.—(*Op. cit. p.* 26.) The *internal inguinal ligament* of Hesselbach is therefore clearly the same thing as the above fascia pointed out by Sir A. Cooper. This point of the abdomen is one of the three weak places on the inside of the inguinal region, where herniæ are liable to occur; yet, weak as it appears to be, it is not the most common situation of such tumours. A computation has been made that, in a hundred cases of inguinal hernia, not ten occur at the point here specified.—(*H. J. Brünninghausen, Unterricht über die Brüche, &c. Wurzb.* 1811.) Mr. Lawrence observes, that if we trace the fascia transversalis from the crural arch upwards, we shall find it divided immediately into two portions, an internal and external, which leave between them a considerable interval just in the middle of the crural arch. The former of these, which is the strongest, and most decidedly fibrous, is connected by its inner edge to the outer margin of the rectus, and to the inferior margin of the tendon of the obliquus internus and transversus; and both are gradually lost above, between the peritoneum and transversus.—(*On Ruptures*, *ed.* 4, *p.* 179.)

The spermatic vessels, joined by the vas deferens, run in front of the epigastric artery, very near the place of its origin. They then pass through the above fascia, go under the edge of the internal oblique and transverse muscles, and next obliquely downwards and forwards, between the above fascia and aponeuroses of the external oblique muscle, to the opening of the ring. When arrived on the smooth surface, immediately behind the ring, they describe an obtuse angle, and pass forwards and downwards into the scrotum.—(*Hesselbach, op cit. p.* 5.)

Thus we see that the spermatic cord, before it actually emerges at what is named the abdominal ring, runs through a kind of canal, to which the epithet *inguinal* is often applied. This oblique passage of the cord, through the abdominal parietes, was well known to, and elegantly delineated by, Albinus; Gimbernat makes distinct mention of it in his *Account of a New Method of operating for Femoral Hernia*, *p.* 19. 32; but Sir A. Cooper has the merit of having given the earliest correct account of the inguinal canal, in reference to hernia; a subject rendered complete by the more recent elucidations of Hesselbach, Scarpa, and Langenbeck.

The abdominal ring is then only the outer opening of the canal or passage, through which the spermatic cord passes before it emerges. The inner one, at which the viscera first protrude, in the most common cases of inguinal hernia, is situated about an inch and a half from the abdominal ring, in the direction towards the anterior superior spinous process of the ilium; or, according to Hesselbach, the inguinal canal is almost an inch and a half in length, the average distance of the outer pillar of the abdominal ring, from the inner pillar of what he terms the posterior ring, being about sixteen lines.—(*Op. cit. p.* 14.) This inner opening is rather nearer the pubes than the ilium, and its upper border is formed by the lower edge of the internal oblique and transverse muscles, which can be plainly felt with the finger, introduced upward and outward into the abdominal ring.

"The precise point at which the hernia most commonly begins," says Scarpa, "is that which corresponds, in the fœtus, to the communication of the tunica vaginalis with the peritoneum, and, in the adult, to the passage of the spermatic cord under the transverse muscle. In the sound state, the peritoneum presents at this part a small funnel-like depression, the depth of which increases in proportion as the spermatic cord is pulled from above downwards. It is this small pouch, this sort of digital appendage, whose progressive augmentation constitutes the hernial sac. Resting upon the anterior surface of the spermatic cord, it first makes its appearance under the inferior edge of the transverse muscle; thence it extends itself in the separation of the inferior fleshy fibres of the internal oblique muscle, always following the spermatic cord, in front of which it is situated; and after having in this manner passed through the whole of the canal, which extends from the iliac region to the pubes, it lastly protrudes at its external orifice, which is the inguinal (or abdominal) ring, properly so called. In all this track, the hernial sac, as well as the spermatic cord, is situated above the femoral arch, the direction of which it follows. The canal which it traverses is of a conical shape, the apex of which is towards the flank, and the base at the external orifice of the ring."—(*Scarpa, Traité des Hernies*, *p.* 44, 45.)

The epigastric artery runs behind the spermatic cord, along the inner margin of the internal opening of the above canal, then upwards and inwards, so as to pass at the distance of half an inch, or an inch, from the upper extremity of the outer opening, or abdominal ring.

In common cases of inguinal hernia, the viscera, protruded at the inner opening of the inguinal canal, lie over the spermatic cord, and form a tumour on the outside of the abdominal ring.

When the viscera have entered the above described digital pouch of the peritoneum, but do not protrude through the abdominal ring, the case is sometimes termed an *incomplete inguinal hernia*; and *complete* when they pass out of that opening. The viscera may continue for a long while quite within the inguinal canal, and even become strangulated there: sometimes, also, they are prevented from passing farther towards the ring by some kind of impediment; and, in this circumstance, if the hernial sac have any addition made

to its contents, it may expand between the external and internal oblique muscles, as Hesselbach had an opportunity of seeing in the body of a female.—(*Ueber den Ursprung, &c. der Leisten-und-Schenkelbrüche, p.* 28.) The stricture may take place either at the internal or external opening of the inguinal canal. In recent and small herniæ, according to Sir A. Cooper, the strangulation is most frequently situated at the inner opening; in large old ruptures, at the abdominal ring. Even when the parts completely protrude out of the latter opening, the strangulation may exist at the inner one: but there may occasionally be two strictures, viz. one at each opening.—(See *Lawrence on Ruptures, p.* 183, *edit.* 3.)

The hernial sac descends through the abdominal ring, over the spermatic cord, and is covered by a fascia, sent off from the tendon of the external oblique muscle. Beneath this fascia, the cremaster muscle is also situated, over the sac, which, after it has descended a certain way, lies on the tunica vaginalis, as well as the spermatic cord.

As the epigastric artery naturally runs first behind the spermatic cord, and then along the inner margin of the internal opening of the ring, and as the viscera are protruded over the cord, they must be situated on the outer side of the artery, which runs first behind the neck of the sac, and then on its inner side. Hence, the inner margin of the sac, when inspected on the side towards the abdomen, seems to be formed, as it were, by the track of the vessel.—(See *Lawrence, p.* 179.) That this is the ordinary situation of the epigastric artery, in relation to the inguinal hernia, is confirmed by the concurrent testimonies of Camper, Chopart, Desault, Sabatier, Sir A. Cooper, Hesselbach, Scarpa, &c. and by preparations to be seen in almost every museum.

In recent inguinal herniæ, the internal and external openings of the ring are at some distance from each other, the first being situated obliquely upwards and outwards in relation to the former; but the pressure of the protruded viscera gradually forces the internal opening more towards the pubes, and nearer to the abdominal ring, so as to render the posterior side of the neck of the hernial sac, and of the inguinal canal, very short.—(*Hesselbach, p.* 29.) Thus, in large herniæ of long standing, the opening into the abdomen is almost direct, and the epigastric artery becomes situated nearer the pubes than in the natural state.

Though such is the ordinary direction in which a bubonocele protrudes, there are occasional varieties. In one of these, the viscera, instead of descending through the canal of the ring, are at once thrust through the abdominal ring itself, and the opening into the belly is then direct; the hernial sac, instead of passing on the external side of the spermatic vessels, as is usual, now lies on their inner or pubic side; and the epigastric artery, which is commonly situated behind, now pursues its course, in front of the sac, at its usual distance from the upper and outer angle of the abdominal ring.

The following is Scarpa's description of the displacement of the epigastric artery in the greater number of cases of inguinal hernia: "This artery, which, in the natural state, runs about ten lines from the abdominal ring, has its situation and direction so changed, in subjects affected with hernia, that it crosses the posterior part of the neck of the hernial sac, and is pushed from the outer to the inner side of the abdominal ring. In order to comprehend the reason of this displacement, it is necessary to recollect what I have elsewhere said of the formation of inguinal hernia, and of the manner in which the spermatic cord crosses the epigastric artery. The hernia begins to form at the very place, where the spermatic cord passes under the inferior margin of the transverse muscle; and this place is rather nearer the flank, than that where the epigastric artery passes towards the rectus muscle. In its progressive extension, the hernial sac constantly follows the same track as the spermatic cord, since it is situated upon its anterior surface. As has been already explained, this cord crosses the epigastric artery; consequently, the hernial sac must necessarily pass with the cord above this artery, before protruding from the canal of the abdominal ring. At the same time, the internal orifice of the hernia becoming larger, and the inguinal canal shortened by the approximation of its two orifices to each other, it follows, that at the period when the hernia begins to make its appearance in the groin, the epigastric artery is unavoidably situated behind the neck of the hernial sac, and is pushed from the outer to the inner side of the ring. Let us suppose a piece of string to be passed from the inside of the abdomen into the scrotum, all through the inguinal canal, and the middle of the hernia; and that this string is pulled so as to bring out the internal orifice of the hernia, which is situated beyond the point where the spermatic cord crosses the epigastric artery; this artery will immediately be found to be carried from the outer to the inner side of the neck of the hernial sac. The same thing happens from the effect of the enlargement of the hernia. The removal of the epigastric artery, from one side of the ring to the other, (says Scarpa,) is a phenomenon which may be regarded as almost constant in the inguinal hernia. I have examined the bodies of a great number of subjects affected with this species of hernia, and it has been only in a very few that I met with the epigastric artery retaining its natural situation on the outer side of the abdominal ring. In investigating the reason of this exception, I have observed, in all the individuals who presented it, a very remarkable weakness and flaccidity of that part of the abdominal parietes which extends from the flank to the pubes. In all, *the displaced viscera had passed through the aponeurosis of the transverse and internal oblique muscles;* not in the vicinity of the ilium, as is commonly the case, but *at a little distance from the pubes*, giving to the upper pillar of the ring a curvature that is extraordinary, and disproportioned to the smallness of the hernia. I observed, also, that the neck of the hernial sac did not pass in an oblique direction, from the flank to the pubes, but that it protruded from the abdomen almost in a direct line from behind forwards. In short, in these individuals, the small cul-de-sac of the peritoneum, which constitutes the origin of the hernial sac, had not begun to be formed under the edge of the transverse muscle, at the point where the spermatic cord runs outward; but *it had passed through the aponeurosis of the internal oblique and transverse muscles, at a little distance from the pubes, and within the point at which the spermatic cord crosses the epigastric artery.* The small hernial sac, having at this part come into contact with and united to the spermatic cord, protruded at the external orifice of the inguinal canal, without displacing the epigastric artery from its natural situation.

"This species of hernia, properly speaking, is a mixture of the ventral and inguinal. It resembles the former, inasmuch as the hernial sac pierces the aponeurosis of the transverse and internal oblique muscles; the latter, inasmuch as it passes out at the abdominal ring, conjointly with the spermatic cord."—(*Scarpa, Traité des Hernies, p.* 68, *&c.*)

Hesselbach particularly adverts to a *triangular space* to be seen on the inside of the inguinal region: the upper boundary of it is formed by the outer edge of the rectus muscle; the lower by the horizontal branch of the os pubis; and the external shortest boundary by the crural vein and epigastric artery. Now, says he, when it is considered, that this artery ascends obliquely inwards, between the inner opening of the ring, and the above triangular space, one cannot fail to know on which side of the neck of the sac the artery must lie in the two species of inguinal, as well as the crural, hernia; for, in those herniæ, which originate in the above triangular space, this artery lies at the outer side of the neck of the hernial sac; while, in every hernia, that takes place through the inner opening of the inguinal canal, the same vessel is situated at the inner side of the neck of the sac. To one species of bubonocele, Hesselbach applies the epithet *external;* and to the other, *internal;* according to the situation of the point at which they first protrude. By Sir A. Cooper, they are named *oblique* and *direct*, which are also very proper terms. The external inguinal hernia is much more frequent than the internal, and is said to occur oftener on the right than the left side of the body; a circumstance coinciding with another observation, viz. that, in children, the tunica vaginalis remains longer open on the right than the left side.

The circumstance of there being two forms of inguinal hernia formerly caused considerable perplexity: surgeons knew, that the epigastric artery lay sometimes at the inner, sometimes at the outer, side of the neck

of the hernial sac, but knew not how to account for this variation. Hence arose the very different opinions about the proper method of dividing the ring when the hernia was strangulated; some authors directing the incision to be made obliquely inwards and upwards, and others, upwards and outwards. But, as a modern writer has judiciously remarked, had they paid greater attention to the direction of the swelling, formed by the neck and body of the hernial sac in the groin, and to the position of the spermatic cord, which is as inconstant as that of the epigastric artery; and had they dissected the parts in the diseased, as well as healthy state; they could not fail soon to have suspected, that every inguinal hernia does not originate exactly at one and the same point. Though the internal bubonocele was occasionally noticed by surgeons many years ago, and Mr. Cline in particular saw an example of it in the year 1777, and always mentioned it in his subsequent lectures, yet the earliest satisfactory history of the differences of the two forms of inguinal hernia was given by Sir A. Cooper, in his great work on ruptures; and the tract, in which Hesselbach pointed out the nature of the internal bubonocele in a very particular manner, I believe is the next publication in which the subject is explained.—(*Anat. Chir. Abhandlung über den Ursprung der Leistenbrüche, Wurzb.* 1806; and *Neueste Anat. Pathol. Untersuchungen über den Ursprung, &c. der Leisten-und Schenkelbrüche, 4to. Wurzb.* 1814, *p.* 18. 26. 28, *&c.*) According to the latter author, since each form of inguinal hernia also presents characteristic appearances externally, the surgeon can have no difficulty in determining the species of hernia; which discrimination must be highly important in the taxis, the application of a truss, and especially the operation. The sac of the external scrotal hernia can only pass down within the expansion of the cremaster as far as this part is separate from the cord and tunica vaginalis. Hence, the testis, covered by its tunica vaginalis, lies under the lowest part of the hernial sac, while the vessels of the spermatic cord, in a more or less separated form, are situated behind the posterior part of the sac; viz. the spermatic veins externally, and the vas deferens internally, and the artery in the middle. Should the hernia descend still farther, the testis being included as well as the sac within the tendinous expansion of the cremaster, it cannot glide out of the way, but must be pressed still farther downwards by the sac, so as to continue invariably under its fundus, but sometimes inclined a little behind it.—(*Hesselbach, p.* 34.) And, as the same author justly observes, the position of the spermatic cord and testis, and the oblique direction of the swelling in the external species, are the two strongest characters by which every case of inguinal hernia may be discriminated. I know of only one case in which the cord was behind the sac, as in the common external bubonocele, and it was seen by Mr. Lawrence. —(*On Ruptures, p.* 210, *edit.* 4.)

Although the spermatic cord, in the external bubonocele, commonly lies behind, or under, the hernial sac, there are cases in which the vas deferens is found on the outer side of it, while the rest of the spermatic cord lies, as it usually does, on the inner side, or rather under it.—(*Cooper.*) Le Dran, Schmucker, and Blizard found the whole cord situated in front of the sac. Sometimes the vas deferens runs on the front and inner part, and the rest of the cord on the back and external part of the swelling.—(*Camper, Hey.*) The cord has been known to be before, and the vas deferens behind, the sac.—(*Camper, A. Cooper.*)

Upon this part of the subject, the reader may deem the following passage interesting. "While the hernia is of moderate size (says Scarpa), the surrounding cellular substance is not very greatly compressed, and no change is observed in the situation of the spermatic vessels. The artery and veins of this name always form, with the vas deferens, one single cord, which is intimately adherent to the posterior surface of the hernial sac. But, in proportion as the tumour increases in size, the cellular substance, which immediately surrounds it, and unites it to the spermatic cord, is more and more distended and compressed. At length, at a certain period, the distention is carried to such a pitch, that the spermatic vessels are separated from one another, and change their position with respect to the hernial sac. This kind of gradual unravelling of the spermatic cord is quite similar to that which would be produced by pulling the surrounding cellular substance in two opposite directions. Such is the reason why, in scrotal hernia of large size, the spermatic artery, the vas deferens, and the spermatic veins are found separated upon the posterior surface of the sac. All these vessels, instead of being conjoined in one cord, are divided by interspaces, which are sometimes very considerable. Ordinarily, the vas deferens is less separated from the spermatic artery than from the vein of this name. In some subjects, Camper has seen it situated on one side of the sac, and the artery and veins on the other.—(*Icones Herniarum, tab.* 5, *L. O. tab.* 8. 1, 2.) The displacement and splitting of the spermatic cord take place equally in adults and in children affected with large scrotal hernia.—(*Camper, loco cit.*) In general, towards the upper part and neck of the hernia, the vessels are not much separated; but, as they proceed downwards, they diverge more and more. Sometimes, when the hernia is very old and bulky, they are no longer found at the posterior part, but rather at the sides, and even on the front surface of the sac; they show themselves through the cremaster muscle, which covers them, and form a kind of vascular train, which arrests the hand of the operator at the moment when he is about to open the hernial sac. Le Dran relates, that in operating upon a large scrotal hernia, he found the spermatic cord on the anterior surface of the hernial sac.—(*Opérations de Chir. p.* 127.) This fact has been the cause of numerous conjectures, and has appeared altogether inconceivable to such surgeons as have not been acquainted with the changes to which the spermatic cord is exposed in cases of large scrotal herniæ. Lassus could not (*Méd. Opérat t.* 1, *p.* 152) conceive the possibility of the occurrence. The observation of Le Dran is not the less true and exact: it exemplifies a very important fact, of which it is easy to give a true explanation, when the state of the spermatic cord, in ordinary inguinal herniæ, and in those which have obtained a considerable size, has been comparatively examined. In the first, the spermatic cord, quite entire, is always situated on the posterior surface of the hernial sac; but in the second, the spermatic vessels are so separated from one another, that they sometimes extend over the sides and even the fore part of the hernial sac."—(*Scarpa, Traité des Hernies, p.* 61, *&c.*)

The hernial sac is commonly described as an elongation of the peritoneum. When more minutely examined, however, it is found, in cases of inguinal hernia, to consist of the portion of peritoneum, pushed out with the viscera; of a layer of cellular substance on the outside of this, which becomes more or less thickened by the pressure of the rupture in different cases; of a fascia, sent off from the tendon of the external oblique muscle; and of the cremaster muscle, which latter parts form the exterior covering, which, consisting of several layers, often leads the operator to fancy that he has opened the cavity of the sac, when, in reality, he has not.

It is observed by Professor Scarpa, that "the cremaster muscle, in cases of old large scrotal hernia, acquires a thickness which is really surprising. Its fibres, which are naturally very thin, become from four to six times more considerable. Being spread over the neck and body of the hernial sac, they sometimes present a remarkable consistence, and a yellowish colour. Such alteration, however, does not prevent the muscular texture from being discovered, and Haller was not mistaken about it."—(*Opusc. Patholog. p.* 317.) Pathology furnishes us with several examples of similar changes of organization. In certain cases, the muscular coat of the bladder, that of the stomach and intestines, and even the exceedingly delicate fleshy fibres of the ligaments of the colon, are found to have become yellow and much thickened.

In old scrotal herniæ (says Scarpa) it is not unusual to find an intimate adhesion of the fibres of the cremaster muscle to the edges of the abdominal ring. This may depend on the pressure, which the contents of the hernia make on those edges, and perhaps it may also depend on the union of the cremaster muscle with the prolongation of the aponeurosis of the fascia lata, which is continued from the margins of the ring to the groin and scrotum. However it may be, certain it is, that in old large scrotal herniæ, there is much difficulty in introducing a probe between the fleshy fibres of the cremaster and the margin of the abdominal ring; and that, on the contrary, in recent herniæ, a

probe passes as easily between the edges of the ring and the cremaster, as between this muscle and the hernial sac.

"Few authors (according to Scarpa) have spoken of the sheath formed by the cremaster muscle, in which are enclosed the hernial sac, the spermatic cord, and the tunica vaginalis of the testicle. Sharp (*in Critical Inquiry*) and Monro, the father (*Anat. and Chirurg. Works*, *p.* 553), were the first to dwell upon this important pathological point. Monro had seen the cremaster muscle covering the hernial sac; but he did not believe that the same thing occurred in all individuals affected with inguinal hernia. In this respect he was mistaken; for this disposition of the cremaster muscle is one of the essential characters of the disease. Petit has not omitted to describe the relations which exist between the cremaster and the hernial sac.—(*Œuvres Posthum. t.* 1, *p.* 288.) On this subject he even relates an interesting fact, from which it results, that, in certain cases, this muscle may by its contractions alone cause a reduction of the hernia. Gunz explains, with tolerable perspicuity, how the cremaster and its aponeurosis form one of the coverings of the inguinal and scrotal hernia.—(*Libellus de Herniis*, *p.* 50.) Morgagni once saw its fleshy fibres extended over the hernial sac (*De Sed. et Caus. Morb. epist.* 34, *art.* 9; *epist.* 31, *art.* 15); and Neubaver positively assures us, that he made the same remark upon the dead body of a man affected with an entero-epiplocele. —(*Dissert. de Epiplo-oscheocele.*) After these facts, so positively and accurately observed, I cannot comprehend (says Scarpa) how in our time Pott, Richter, and several other authors should have passed over in silence, or only mentioned vaguely, this point, so important in the history of the inguinal and scrotal hernia."—(*Scarpa, Traité des Hernies*, *p.* 48—50.)

When surgeons speak of a hernial sac being usually thicker and stronger, in proportion to the magnitude and duration of the hernia, their language is not at all correct; for, in fact, the peritoneal investment of the hernia is seldom or never thus altered. I can declare (says Scarpa), after numerous observations, that, in the majority of cases, the hernial sac, strictly so called, is not perceptibly thickened, and that in general it does not differ from other parts of the peritoneum, however large and old the scrotal hernia may be.—(*Traité des Hernies*, *p.* 53.)

In a very enormous hernia, the pressure of the contents is so great, that instead of thickening the sac, it renders it thinner, and even makes it ulcerate. The protruded viscera have been met with immediately beneath the integuments, when the sac has been burst by a blow.—(*Cooper, J. L. Petit.*)

The outer surface of the peritoneal part of the hernial sac is always most closely adherent to the other more external covering by means of cellular substance. This connexion is formed so soon after the first occurrence of a hernia, that any hopes of returning a hernial sac into the abdomen have generally been considered as chimerical. There must, however, be a certain space of time before adhesions form, though it must be exceedingly short.

Upon this point, Scarpa does not adopt the opinion that has commonly prevailed.

There is no doubt, he observes, that in recent and small inguinal herniæ, the intestine, strangulated by the neck of the hernial sac, has been known, in more instances than one, to have been reduced by the taxis, and carried with it the whole of the sac into the abdomen. Observations not less authentic inform us, that after the operation for hernia, when the viscera could not be reduced on account of their adhesions to the sac, they have been seen, notwithstanding such adhesions, to get nearer to the ring daily, and, at length, spontaneously to return into the belly together with the hernial sac. Louis, he thinks, was wrong in denying the possibility of these facts.—(*Acad. Royale de Chir t.* 11, *p.* 486.)

Scarpa argues, that "under certain circumstances the cellular substance will bear, without laceration, a considerable elongation, and afterward shrink again." Thus we often see a viscus which has suffered a considerable displacement, return spontaneously into its natural situation. In the inguinal hernia, the spermatic cord is elongated, and descends farther than in the natural state. No laceration of the cellular substance, however, is then occasioned; for if the hernia be kept reduced, the spermatic cord becomes shorter, daily retracts, and at last has only the same length which it had previously to the disease. When a sarcocele becomes large and heavy, the portion of the spermatic cord naturally situated within the belly is by degrees drawn out into the scrotum; but after the tumour is extirpated, this portion ascends again, and of itself returns into its original situation.

The same thing happens after the operation for the strangulated inguinal hernia. All practitioners have noticed, that the hernial state retracts and reascends progressively towards the ring. This alone would prove, that the cellular substance which surrounds the spermatic cord, and unites it to the hernial sac, is highly endued with the property of yielding, and afterward returning to its original sac. Can the same property be refused to the cellular substance which unites the sac to the cremaster muscle and other surrounding parts?

"While the inguinal hernia is recent, and not of much size, the cellular substance in question possesses all its elasticity, and hence, the hernial sac and the spermatic cord may easily ascend towards the abdominal ring. I have had occasion (says Scarpa) to make this observation upon the dead body of a man who had an incipient inguinal hernia. The small hernial sac was capable of being pushed back into the ring with the utmost facility; and in carefully examining the parts, both within and without the belly, it appeared to me, that the cellular substance which united the sac to the spermatic cord and cremaster muscle, was disposed to yield equally from without inwards, and in the direction precisely opposite; that is to say, it made an equal resistance to the protrusion and the reduction of the hernial sac. Monteggia has seen a case exactly similar; although, according to his own expressions (*Instituz. Chirurg. t.* 3, *sec.* 2, *p.* 249), the hernial sac was not very small, it adhered very loosely to the surrounding parts, and it admitted of being entirely reduced into the abdomen with great facility."

In large old scrotal herniæ, Scarpa allows, that such reduction is quite impracticable: "In these, the cellular substance which unites the sac to the spermatic cord and cremaster muscle, has acquired such a density, that it does not oppose less resistance to the further enlargement of the hernia, than to the efforts of the surgeon who endeavours to effect its reduction." —(*Scarpa, Traité des Hernies*, *p.* 57, &c.)

In the dead subject, Cloquet found the sac of an internal inguinal hernia reduced into the abdomen, whither it seemed to have been drawn by a piece of omentum adherent to what had, in its protruded state, been its fundus.—(*Recherches sur les Causes, &c. des Hernies*, *p.* 102.) The investigations of the same author prove, that complete or incomplete inversions of the sac may also happen in the femoral and internal inguinal hernia, without the existence of any adhesion; but that the intimate union between the sac and spermatic cord hinders the event in external or common inguinal ruptures. Le Dran dissected a case, in which the sac of a femoral hernia, with its contents, had been returned into the abdomen in a mass. The observations of Cloquet also tend to confirm the possibility of the latter occurrence, which he describes as happening with more facility in the internal inguinal rupture than in the crural, and with most difficulty in the external inguinal hernia.

We shall conclude this anatomical account of the inguinal hernia, with the following explanation of the parts as they appear on dissection: "The removal of the integuments exposes the exterior investment of the hernial tumour, continuous with the margins of the ring, and formed of tendinous fibres from the aponeurosis, the cremaster muscle, &c. This is connected by cellular substance with the proper hernial sac, formed of the peritoneum. This production of the peritoneum passes within the ring of the external oblique, and then goes upwards and outwards. Behind and above the ring, the inferior margin of the obliquus internus and transversalis crosses the neck of the sac. When these muscles are reflected towards the linea alba, the fascia, ascending from Poupart's ligament, and forming the upper opening of the ring, is exposed, and the epigastric artery is discovered emerging from the inner side of the neck of the hernial sac (*Camperi Icones*, *tab.* x. *F. M.*), which, at this precise point, becomes continuous with the peritoneum

dining the abdomen. The removal of the hernial sac will disclose the course of the spermatic cord in its descent towards the testicle; and when this is also elevated, the first part of the course of the epigastric artery, and its origin from the iliac trunk, are exposed." —(*Lawrence on Ruptures, p.* 203, *ed.* 4.)

In females, when a bubonocele occurs (which is uncommon), the round ligament of the uterus bears the same relation to the tumour, as the spermatic cord in males. According to Sir Astley Cooper, the sac is much more considerable above the abdominal ring than below it; and hence difficulty in the operation. All the cases which he has seen have been intestinal. The stricture is, in almost all cases, at a considerable distance above the abdominal ring; it may be divided upwards or outwards with safety, as the epigastric artery is situated more towards the linea alba.—(See *Lancet, vol.* 2, *p.* 172.)

Mr. Lawrence had a very rare instance pointed out to him, in which a bubonocele in a female was situated on the inner side of the epigastric artery. A still rarer case was examined by Hesselbach: it was not only an example of internal bubonocele in a woman, but of one in which the epigastric artery arose from the obturatrix artery, an inch from the origin of this latter vessel from the inner side of the external iliac; the obturatrix first passed an inch obliquely downwards and inwards over the crural vein, and immediately afterward, on the horizontal ramus of the pubes, made a sudden turn backwards and downwards to the obturator foramen; and at this bend rose the epigastric artery, which ran transversely inwards along the horizontal ramus of the pubes, behind the neck of the hernial sac, at the inner side of which it ascended to the rectus muscle, accompanied by the ligamentous remains of the umbilical arteries which were close behind it.—(*Ueber den Ursprung, &c. der Leisten- und-Schenkelbrüche, p.* 17.)

MARKS OF DISCRIMINATION BETWEEN INGUINAL HERNIÆ AND OTHER DISEASES.

The disorders, in which a mistake may possibly be made, are *Cirsocele, Bubo, Hydrocele,* and *Hernia Humoralis*, or *Inflamed Testicle.*

For an account of the manner of distinguishing the first complaint from a bubonocele, see *Cirsocele.*

"The circumscribed incompressible hardness, the situation of the tumour, and its being free from all connexion with the spermatic process, will sufficiently point out a bubo, at least while it is in a recent state; and when it is in any degree suppurated, he must have a very small share of the *tactus eruditus*, who cannot feel the difference between matter, and either a piece of intestine or omentum.

"The perfect equality of the whole tumour, the freedom and smallness of the spermatic process above it, the power of feeling the spermatic vessels and the vas deferens in that process, its being void of pain upon being handled, the fluctuation of the water, the gradual formation of the swelling, its having begun below and proceeded upwards, its not being affected by any posture or action of the patient, nor increased by his coughing or sneezing, together with the absolute impossibility of feeling the testicle at the bottom of the scrotum, will always, to an intelligent person, prove the disease to be a hydrocele." The transparency of a hydrocele is also another criterion. Mr. Pott, however, allows, that there are some exceptions, in which the testicle cannot be felt at the bottom of the scrotum, in cases of hernia. "In recent bubonoceles, while the hernial sac is thin, has not been long or very much distended, and the scrotum still preserves a regularity of figure, the testicle may almost always be easily felt at the inferior and posterior part of the tumour. But in old ruptures which have been long down, in which the quantity of contents is large, the sac considerably thickened, and the scrotum of an irregular figure, the testicle frequently cannot be felt, neither is it in general easily felt in the *congenital hernia* for obvious reasons."—(*Pott.*)

Attention to these circumstances is highly necessary in practice, as the mistaking of a hernia for a hydrocele may, and has been, the cause of fatal accidents. A case, confirming this fact, is mentioned by Sir A. Cooper.—(See *Lancet, vol.* 2, *p.* 112.) Hydrocele of the spermatic cord is another case still more likely to be taken for a hernia, than the common form of hydrocele.—(See *Hydrocele.*)

[This is an error of more frequent occurrence than is generally known or even supposed. Dr. J. B. Davidge, late Professor of Anatomy in the University of Maryland, related in his lectures, that he had frequently been consulted by persons who had been wearing trusses for years, by the advice of surgeons who had accused them of hernia, when the disease was purely "hydrocele of the spermatic cord;" and in one case the sac had been burst by the violent efforts made to reduce it. I have known this mistake committed several times, and shall never forget one instance of the performance of the operation by an English surgeon possessed of both skill and experience, and after dissecting down to the hernial *sac*, as he thought, with suitable caution, he discovered his error; not however until he had divided the tendon of the external oblique for half an inch, when the hydrocele gave way, and emptied its contents. He was deceived by the long and obstinate constipation, nausea, vomiting, hiccough, abdominal distention, and other symptoms of strangulation, which indeed were sufficient, with the tumour in the groin, which had now become painful, to defeat any ordinary faculty of discrimination, and made the diagnosis exceedingly difficult. And it is but just to add, that he was sent for in the night on purpose to operate, after the taxis had been ineffectually applied, and the patient was alarmingly situated. He had the magnanimity to acknowledge his error, and the patient subsequently recovered under bleeding and the antiphlogistic battery, never suffering any inconvenience from the wound of the operation; indeed benefited thereby, since it cured his hydrocele of the cord.—*Reese.*]

"In the *hernia humoralis*, the pain in the testicle, its enlargement, the hardened state of the epidydimis, and the exemption of spermatic cord from all unnatural fulness, are such marks as cannot easily be mistaken; not to mention the generally preceding gonorrhœa. But, if any doubt still remains of the true nature of the disease, the progress of it from above downwards, its different state and size in different postures, particularly lying and standing, together with its descent and ascent, will, if duly attended to, put it out of all doubt, that the tumour is a *true hernia.*"—(*Pott.*)

INGUINAL HERNIA WITHIN THE CANAL.

When the parts only protrude into the inguinal canal, and not out of its lower aperture, they are covered by the aponeurosis of the external oblique muscle. The transverse and internal oblique muscles pass over the neck of the hernia, and cause the strangulation when it happens. The tumour is small; for, if the protrusion increases, the parts escape through the lower opening of the canal. Exceptions, however, are on record. Thus, Mr. Lawrence dissected a case in a female, where the aponeurosis of the external oblique was distended by a swelling equal in bulk to two fists, while another portion of the sac, as large as an egg, projected through the ring. Hesselbach's 8th plate also represents a hernia within the canal, of considerable size, in a female. As, in the ordinary circumstances of this form of inguinal hernia, there is no very manifest swelling, the case is no doubt very often looked upon and treated, as Sir Astley Cooper remarks, as an inflammation of the bowels.—(*On Inguinal and Congenital Hernia, p.* 48.)

When an inguinal hernia does not descend through the abdominal ring, but only into the canal for the spermatic cord, it is covered by the aponeurosis of the external oblique muscle, and the swelling is small and undefined.

Now and then, the testicle does not descend into the scrotum till a late period, and its first appearance at the ring, in order to get into its natural situation, may be mistaken for a hernia; unless the surgeon pay attention to the absence of the testicle from the scrotum, and the peculiar sensation occasioned by pressing the swelling.

POINTS OF DIFFERENCE BETWEEN THE EXTERNAL AND INTERNAL INGUINAL HERNIA, &c.

According to Hesselbach, the characteristic marks of the external bubonocele and scrotal hernia, are, 1st. The direction of the tumour in the groin. 2dly. The fleshy fibres of the cremaster. 3dly. The position of

the spermatic cord and testis. 4thly. The situation of the epigastric artery. 5thly. The origin of the hernia itself. 6thly. A preternatural shape of the body of the hernial sac.

1. The neck of the hernial sac, distended by the protruded viscera, raises up the front side of the inguinal canal, and superincumbent integuments, into an oblong swelling, which extends obliquely inwards and downwards towards the abdominal ring, and terminates in the tumour formed by the body of the hernial sac. From its origin it becomes gradually more prominent and broad; and the greater the quantity of viscera protruded, and the larger the body of the sac, the more manifest is this oblique swelling, particularly when the neck of the hernia is of its natural length. In strangulated cases, the direction of the tumour is still more striking, every part of the hernial sac being then considerably distended. When the inguinal canal, and of course the neck of the hernial sac is shortened, the swelling undergoes a proportional diminution in its length; and then its resemblance to the tumour attending an internal inguinal hernia, where the opening through which the parts pass is long and slanting, is so great, that the cases can only be discriminated by one circumstance, viz. the situation of the spermatic cord; and even this criterion is of course wanting in females. —(*Hesselbach, p.* 57, 58.) Hesselbach clearly explains, that the obliquity of the swelling is seated in the neck of the hernial sac. He observes, that when an internal bubonocele in a female subject passes into the labium, the descent takes place in a very sloping direction inwards, and therefore may at first be supposed to be an external case. But on further examination, the oblique swelling will be found to occupy the body of the hernial sac, and to reach upwards and outwards from the labium to the abdominal ring. Now this hernia cannot be mistaken for an external bubonocele, the course of which from the ring is obliquely upwards and outwards. As Sir A. Cooper has remarked, if there be any obliquity of an internal inguinal hernia, it will incline towards the linea alba.—(See *Lancet, vol.* 2, *p.* 109.)

Hesselbach reminds us, that an internal inguinal or scrotal hernia, may be conjoined with an external incomplete bubonocele; a kind of case easily made out with a little attention; for the place of division between the two sacs is indicated by a more or less deep groove. The nature of the disease will also be still clearer, if one of the tumours admit of reduction. A specimen of such a double hernia is to be seen in the museum at Würzburg.

It is further noticed by Hesselbach, that when the situations of the external and internal hernie are compared, the first of these swellings will be found to be rather farther than the other from the symphysis of the pubes; a difference ascribed to the effect of the internal oblique muscle, the lower fibres of which, attached to the horizontal ramus of the pubes, run in a curved direction transversely over the anterior and inner part of the neck of the hernial sac, and are applied so closely to it, that it cannot approach quite so much towards the symphysis of the pubes, as the neck of the internal bubonocele does. The muscular fibres in question are situated directly behind the inner pillar of the abdominal ring.

2. Most of the fibres of the cremaster lie on the back of the neck of the sac, but others are also scattered over its external and internal sides. Some fibres may also be perceived on its fore part, which are remarkable, because they run in a transverse curved direction, with their convexity downwards, and two fasciculi of which descend below the abdominal ring. These are the fibres of the cremaster, which proceed within the ring transversely upwards over the spermatic cord, and are pushed out of that opening by the hernial sac. These arched fleshy fibres are not always, though generally, perceptible; and when they are present on the fore part of the hernial sac, Hesselbach accounts them a sure criterion of an external scrotal hernia; but he has not yet ascertained whether they are visible while the rupture is confined to the groin.

3. The situation of the spermatic cord and testis in the external inguinal hernia, and,

4. That of the epigastric artery, and its displacement inwards by the neck of the sac, have been sufficiently explained.

5. With respect to the mode in which the hernia originates, the disease often takes place suddenly, without any exciting cause being observed capable of accounting for the effect. Here, says Hesselbach, the predisposing cause must have been great; for instance, the communication between the cavity of the peritoneum and that of the tunica vaginalis has remained a long while unclosed; and when a hernia of this description is examined, the other marks of an external inguinal hernia are associated with the sudden formation of the disease. In this quick manner the congenital hernia, which is one of the external cases, frequently arises The internal inguinal hernia is also observed mostly to take place very suddenly, yet only after violent occasional causes. According to Sir Astley Cooper, it arises more frequently from the efforts made to expel the urine, in cases of stricture, than from any other cause.—(See *Lancet, vol.* 2, *p.* 141.)

6. A preternatural form of the body of the hernial sac, Hesselbach remarks, is particularly seated in the sheath of the spermatic cord, and can never happen in the internal scrotal hernia; for it is only in external cases that the above sheath is ever converted into the hernial sac. Hesselbach here refers to the partial contraction often noticed at the lower part of the above sheath in cases of congenital hernia; a circumstance which is always discovered previously to the business of dividing the ring.

In adults, an external inguinal or scrotal hernia, on the right side, contains some of the ilium, and, when the swelling is large, it may include the cœcum, and sometimes a piece of omentum. In one child, ten weeks old, and in another still younger, the appendix vermiformis was protruded and connected by a natural band to the posterior side of the peritoneum. When, in these ruptures of the right side, the cœcum, or, in those of the left, the colon, are met with closely adherent to the hinder side of the hernial sac, the adhesion is not to be looked upon as the effect of disease, since it is the perfectly natural connexion of those bowels with the peritoneum. On the left side, the parts most commonly protruded are the colon and omentum

With regard to the *internal inguinal hernia*, the place of its first protrusion has been already described. The protruded peritoneum and viscera, according to Hesselbach's account, *pass from behind straight forwards*, between the fibres of what he names the internal inguinal ligament, and the fleshy fibres of the internal oblique muscle: they then pass, at the inner side of the spermatic cord, out of the abdominal ring, where the hernia presents *a circular globular swelling, suddenly formed in consequence of some violent effort.* The neck of the hernial sac is very short; shorter than it can ever be in an external inguinal hernia; and when the tumour is of the above shape, the passage through which it passes is annular, narrower in some instances than others, and its margin is tendinous. From the few cases which Hesselbach has seen of this form of the disease, he is led to conjecture, that the hernial sac is rarely so large as in the external inguinal hernia.—(*P.* 41.) According to Sir Astley Cooper, the internal inguinal hernia occurs when the tendon of the transversalis is unnaturally weak, does not exist at all, or has been broken.—(*On Inguinal Hernia, p.* 51.) Cloquet states, that the sac either propels before it, and thus receives a covering from the fascia transversalis, or passes through an opening in it. —(*Recherches Anat. p.* 83.) Mr. Lawrence dissected a case, where the fascia was neither thinner than usual, nor broken, but it had been protruded before the peritoneum, and formed a thick aponeurotic covering to the hernial sac. Mr. Stanley has always found it thus covered, and some specimens, illustrative of the fact, have been placed by him in the museum of St. Bartholomew's Hospital.—(*On Ruptures, p.* 209. 211, *ed.* 4.) According to Langenbeck, this is the usual state of the parts.—(*Comment.* § 165, *tab.* 17, 18, 19.) Sir Astley Cooper, in his lectures, also describes the hernia as having an investment, one half of which is formed by the tendon of the transversalis, and the other half by the fascia transversalis.—(See *Lancet, vol.* 2, *p.* 140.) The earlier dissections made by Hesselbach, led him to suppose, that in the internal inguinal hernia, the opening through which the protrusion happens is always annular, and the swelling in front of the ring globular; but subsequent cases which he has met with have informed him that the opening is frequently sloping and longish; in which circumstance, the re-

semblance of the tumour to that of the external bubonocele with a shortened neck is such, that the only mark of distinction between the two cases is the position of the spermatic cord. In females, even this criterion is of course deficient.—(*Hesselbach, p.* 57.) Though individuals of almost every age are subject to internal bubonoceles, they are much less common than external cases. According to Hesselbach, they may be known by the following characters: 1. The swelling, formed by the body of the hernial sac, immediately in front of the abdominal ring. 2. The situation of the spermatic cord. 3. That of the epigastric artery.

1. The neck of the hernial sac, besides being very short, does not, like that of an external inguinal hernia, take an oblique direction, but advances straight from behind forwards through the abdominal ring; and as the body of the sac lies directly over the neck, none of the swelling formed by the distention of the latter part, can be felt. Nor does any other tumour, produced by the body of a hernial sac, ever cause a circular spherical swelling directly before the abdominal ring. The situation of the neck of this kind of hernia must already apprize us, that the internal bubonocele is nearer than the external to the symphysis of the pubes. In women the shape of the tumour is the only character, by which the case can be distinguished.—(*Hesselbach, p.* 43.)

2. After what has been already stated, respecting the situation of the spermatic cord in the internal inguinal hernia, I shall merely notice one or two observations of Hesselbach. The cord lies either upon the outer side, or outer half of the fore part of the upper portion of the hernial sac, the blood-vessels forwards, and the vas deferens backwards. When the sac is adherent to the whole length of the cord, the testis is not situated under the fundus of the sac, as in the external scrotal hernia, but either at the fore part or outer side of the body of the sac. The hernial sac, as far as the abdominal ring, is excluded from the common peritoneal covering of the spermatic cord, but, at this opening, it descends between the cord and the internal thin part of the sheath of the cremaster, which, however, is somewhat stronger towards the front and outer side of the hernia, over which part alone the fleshy fibres of the cremaster are spread.—(*P.* 44.)

3. The epigastric artery always ascends obliquely inwards at the outer side of the neck of the hernial sac. Hesselbach has never seen but one case of internal bubonocele, in which there was a deviation from this rule. The example has been already mentioned, and was one in which the epigastric artery arose from the obturatrix about an inch from the origin of this last vessel. The viscera usually contained in an internal inguinal or scrotal hernia, on the right side, are the lower part of the small intestines, and sometimes omentum; on the left, a part of the small intestines, frequently omentum, and, when the tumour is large, the colon may also protrude. A protrusion of the bladder may accompany the disease, but that organ is of course always excluded from the cavity of the hernial sac. When the remains of the umbilical cord are situated more outwards than usual, and lie over the centre of the space at which the protrusion happens, an internal bubonocele may be double, the prolapsus happening on each side of that ligamentous substance, which is itself also pushed outwards. In consequenee of the accidental presence of some very strong tendinous fibres at the centre of the fascia, called by Hesselbach the internal inguinal ligament, there may also be two distinct protrusions, with separate hernial sacs. —(*P.* 46.)

When the surgeon, by a due consideration of the foregoing circumstances, has formed a judgment respecting the nature of the hernia, he will be better qualified to regulate the treatment of the case. Thus, in the external inguinal hernia, he will know, that the pressure employed for the reduction of the bowels should be made in the direction of the neck of the hernial sac, viz. obliquely upwards and outwards towards the anterior superior spinous process of the ilium; but that, when the neck of the same kind of hernia is very short, and the posterior side of the inguinal canal has been removed, the pressure should be made nearly in a straight line from before backwards. For what Hesselbach terms the long necked external inguinal hernia, the pad of a truss should be so constructed, as not merely to press upon the abdominal ring, but also upon the neck of the sac and the inner opening of the inguinal canal. But when the neck of the hernia is very short, the pad should be nearly of the same form as that required for an internal inguinal hernia.—(*Hesselbach, p.* 38; and *Brünninghausen, Gemeinnütziger Unterricht über die Brüche, &c. Würzb.* 1811.) In attempting the reduction of an internal inguinal hernia, the pressure should be directed nearly straight backwards: and the pad of the truss should only act upon the abdominal ring.—(*Hesselbach, p.* 46.) It is a case in which the intestine often continues strangulated, after the reduction, within the ring.—(*Sir A. Cooper;* see *Lancet, vol.* 2, *p.* 142.)

THE OPERATION FOR STRANGULATED INGUINAL HERNIA, OR BUBONOCELE.

Sir Astley Cooper particularly recommends operations for strangulated herniæ to be performed before any peritoneal tenderness exists, which renders the issue very doubtful, though the parts be liberated by the division of the stricture. Such tenderness is not to be confounded with the tension produced by the inflation of the intestines. In old persons, the operation may be deferred longer than in the young or the middle-aged.—(See *Lancet, vol.* 2, *p.* 142.) The operation consists in dividing the integuments; dissecting down to the sac, and opening it; removing the stricture; and replacing the protruded viscera. The hair is first to be shaved from the pubes.

The external incision should begin an inch above the external angle of the ring, and extend over the middle of the tumour to its lower part, except when the swelling is large; in which circumstance, the cut need not extend so far down, as will be presently noticed. The advantage of beginning the wound so high, is to obtain convenient room for the incision of the stricture. By this first cut, the external pubic branch of the femoral artery may be divided: it crosses the hernial sac near the abdominal ring, and sometimes bleeds so freely as to require to be immediately tied. In general, however, a ligature is unnecessary.

When this incision is carried low down, the caution, given by Camper, should always be remembered, viz that there is a possibility of dividing the spermatic vessels, should they happen to be situated, as they sometimes are, in front of the hernia. And in order to avoid such an accident, which is particularly apt to occur in cases of internal inguinal or scrotal hernia the incision through the skin should be made obliquely downwards and inwards.—(*Hesselbach, p.* 46.) The division of the integuments brings into view the fascia, which is sent off from the tendum of the external oblique muscle, and covers the hernial sac.

The layers of tendinous fibres, cellular substance, &c. intervening between the skin and sac, should be carefully divided, one after another, with the knife and dissecting forceps; the edge of the former instrument being turned horizontally, lest the incisions be carried too deeply at once, and the viscera contained in the sac wounded.

After making a small opening through a part of the fascia covering the sac, some practitioners introduce a director, and divide this fascia upwards and downwards, as far as the tumour extends. The same manner they next pursue with regard to the cremaster muscle. Thus the sac becomes completely exposed. When this method is followed, Sir A. Cooper advises the incisions not to be carried upwards nearer than one inch to the abdominal ring, for reasons which will be presently explained.

However, it may be rationally doubted, whether there is any good in these formal and successive divisions of the whole length of the coverings of the sac; and it is certain that they protract the operation very much; for the manner in which the sac adheres to the outer investment of it, prevents the latter from being raised and cut without trouble and delay. As the grand object, after the skin has been divided, is to make a small opening into the sac, sufficient for the introduction of a director, dissecting down at one particular place answers every purpose, and enables us, in the end, to lay open the whole of the sac and its coverings in the shortest time. Let the operator only take care to raise the successive layers of fibres with the forceps, and divide the apex of each elevated portion with the knife held horizontally. As there is commonly a quantity of fluid in the sac, and it gravitates to the lower part, to which the intestine seldom quite de-

scends, this is certainly the safest situation for making the first opening into the sac. The operator, however, should not rely upon the presence of such fluid, and cut too boldly; for sometimes it is absent, and the viscera may be in immediate contact with, nay, adherent to, the inner surface of the sac.

The circular arrangement of the vessels of a piece of intestine, and its smooth polished surface, sufficiently distinguish it from the hernial sac, which has a rough cellular surface, and is always connected with the surrounding parts, although these adhesions, in a very recent case, may be but slight.—(*Lawrence on Ruptures, p. 232, edit.* 4.)

I have mentioned that Sir A. Cooper only advises cutting the fascia and other coverings of the sac, under the skin, to within an inch of the abdominal ring; and, of course, he also recommends limiting the division of the sac itself to the same extent. His reasons for this practice are, to avoid making the closure of the wound more difficult, and to lessen the danger of peritoneal inflammation.

Having laid open the hernial sac, with a probe-pointed bistoury, guided by a director, or the fore-finger, introduced into the opening made at the lower part of the sac, the next desideratum is to divide the stricture, unless the viscera admit of being easily reduced, without such an incision being made as occasionally happens.

From the anatomical account which has been given of the bubonocele, it appears, that the stricture may either be situated at the abdominal ring, and be formed by the margins of this opening, or else at the inner aperture of the canal, about one inch and a half, in a direction upwards and outwards, from the outer opening in the tendon of the external oblique muscle. This latter strangulation is caused by the semicircular edge of the transversalis muscle and its tendon, which pass over the neck of the hernial sac, and by a fascia, arising from Poupart's ligament, the semicircular border of which passes under this part of the sac.

The common, and probably the best, practice is to divide the hernial sac, together with the stricture. When this is situated at the abdominal ring, the surgeon is to introduce the end of a director a little way into the neck of the sac, within the aperture in the tendon, and with a probe-pointed bistoury, guided on the latter instrument, *he is to cut the stricture upwards and outwards, or else directly upwards;* a manner which Sir A. Cooper recommends, because it is applicable to all cases, even the less frequent ones, in which the hernia protrudes at the inner side of the epigastric artery; and in all common instances, we know, that this vessel runs upwards round the inner side of the neck of the sac; a course prohibiting the division of the stricture upwards and inwards.

In the external inguinal hernia, the method of cutting the stricture upwards and outwards is perfectly safe; but when the case is what Hesselbach calls internal, and the viscera descend on the inner side of the epigastric artery, it is a plan which would endanger the latter vessel, and ought never to be adopted, notwithstanding any statement made in its favour by Rudtorffer.—(*Abhandlung über die einfachste und sicherste Operations-Methode eingesperrter Leisten-und-Schenkelbrüche. Wien*, 1808.) In this work, the erroneous plan of cutting the ring inwards is inculcated, both in the external and internal inguinal rupture. The author, however, seems to have performed many operations in this manner, without any accident from hemorrhage; a piece of good fortune which Professor Langenbeck ascribes to the circumstance of the knife having always been applied, as Rudtorffer directs, to the middle of the inner pillar of the ring, and to the cut having been very limited. Langenbeck is of opinion, that if the knife had been applied a little lower, and the incision carried to any extent, the epigastric artery, in ordinary cases, would not have escaped injury. Sir A. Cooper's rule of always cutting in one direction, viz. upwards, which I believe was first advised by Rougemont, and afterward by Autenrieth (*Dissert. Moment. circa Herniotom, præcipue circa evitandam Art. Epigastr. Læsionem, Tub.* 1799), is perhaps a very good one, because it is at least easy for the memory, and will answer very well, even when it is not in the power of the surgeon to pronounce positively, whether the case is a short-necked external bubonocele, or an internal one with an oblong oval fissure, cases having a great external resemblance, especially in women, in whom there is not the spermatic cord as a criterion; for, after all, this part, when present, is the surest guide, and that on which Desault founded his perfectly safe advice, viz. when the cord is at the posterior or inner side of the neck of the hernial sac, to divide the ring upwards and outwards, but inwards and upwards when it lay at the outer or on the fore part of the sac. —(*Œuvres Chir. par Bichat, t.* 2.) At all events, this advice is subject but to one exception, which is the very rare one of the epigastric running round the inner side of the neck of the sac in an internal bubonocele; a possibility which has been already explained, and which leads Hesselbach particularly to recommend the division of the ring, in every internal inguinal hernia, to be made straight upwards.—(*P.* 47.) Indeed, the long-necked external bubonocele is the only case in which he thinks the latter plan should give way to that of cutting upwards and outwards. The safety and propriety of the method of always cutting upwards are strikingly illustrated by what Scarpa observes: he states, that the right direction of the incision of the ring is directly upwards, parallel to the linea alba. "I have (says he) operated in the way which I recommend, upon several dead subjects, who had either external or internal inguinal herniæ, directing my incision in the course of a line drawn from the upper part of the ring parallel to the linea alba: in all, I constantly left the epigastric artery untouched, even when I extended the cut about an inch above the inguinal ring."—(*Scarpa, Traité Pratique des Hernies, p.* 111.) Only one objection, as far as I know, has been made to this plan, and it is founded on the alleged impossibility of introducing the knife, so as to cut straight upwards, when the neck of the hernial sac is long, because then the posterior side of the inguinal canal is in the way.—(*Hesselbach, p.* 40.) No more of the parts forming the stricture should be cut than is just sufficient for allowing the protruded viscera to be reduced, without bruising or otherwise hurting them; and I consider the middle of the upper margin of the ring the safest place for making the necessary incision.

Sir A. Cooper, in his valuable work on the Inguinal Hernia, advises a mode of dividing the stricture, considerably different from the usual method. He directs the finger of the operator to be introduced into the sac (which in his plan, we know, is left undivided for the space of one inch below the ring). When the stricture is felt, a probe-pointed bistoury is to be conveyed over the front of the sac into the ring (between the two parts), and the latter only is then to be divided, in the direction upwards, opposite the middle of the neck of the sac, and to an extent just sufficient to allow the protruded parts to be returned into the abdomen, without their being hurt. The two chief advantages which Sir A. Cooper imputes to this method are, that the danger of peritoneal inflammation will be less, and that the epigastric artery, if wounded, would not bleed into the abdomen. I am of opinion, that Mr. Lawrence's remarks concerning this proposal are judicious: an accurate comparative trial of both methods would be necessary, in order to determine the weight of the first reason. The second circumstance cannot be a matter of any importance, if we cut in such a direction as will avoid the risk of wounding the artery. Many circumstances present themselves as objections to this proposal. The manœuvre itself, although perhaps easy to the experienced hand of so able an anatomist as Sir A. Cooper, would, I am convinced, be found highly difficult, if not impracticable, by the generality of surgeons. This difficulty arises from the firm manner in which the sac and surrounding parts are connected, we might almost say, consolidated together. The experience of Richter (*Traité des Hernies, p.* 118) shows, that this objection is founded in reality. He once tried to divide the ring without cutting the sac, but he found it impracticable. If the stricture is so tight as to prevent the introduction of the finger, there must be great danger of wounding the protruded parts. The practice would still be not advisable, even if it could be rendered as easy as the common method of operating Sir Astley leaves an inch of the sac below the ring undivided: thus a bag remains ready to receive any future protrusion, and the chance of a radical cure is diminished. It would be better to follow the advice of Richter, and scarify the neck of the sac, in order to promote an adhesion of its sides. He has found this

practice so successful in accomplishing a radical cure, that he advises (*p.* 191) its employment in every operation for strangulated hernia.—(See *Lawrence on Ruptures*, *p.* 249, *edit.* 4.)

If the stricture should be at the inner opening of the canal for the spermatic cord, Sir A. Cooper advises the operator to introduce his finger into the sac as far as the stricture, and then to insinuate a probe-pointed bistoury, with the flat part of its blade turned towards the finger, between the front of the sac and the abdominal ring, till it arrives under the stricture formed by the lower edge of the transversalis and obliquus internus. Then the edge of the instrument is to be turned forwards, and the stricture cut in the direction upwards. This plan of not cutting the neck of the sac is liable to all the objections stated by Mr. Lawrence, in regard to the case in which the strangulation takes place at the abdominal ring. Sir A. Cooper's bistoury is a very proper one for dividing the stricture, as it only has a cutting edge to a certain distance from the point. Perhaps, on the whole, we may infer, that it is both most easy and advantageous to divide the neck of the sac, together with the stricture, whether this be situated at the ring or more inwards. The method of cutting the stricture from without inwards I consider objectionable, on the ground of the risk of wounding the bowels in this mode being greater than that of any accident from wounding the epigastric artery, when it arises in an unusual manner, and deviates from its regular course; a reflection which has made Dr. Hesselbach, junior, an advocate for the practice.—(See *Sicherste Art des Bruchschnittes*, *4to. Bamberg*, 1819.)

When the stricture is at the upper opening of the inguinal canal, the ring should not be cut, unless it prevent the operator from reaching the more deeply seated strangulation, as happened in a case recorded by Mr. Lawrence.—(*On Ruptures*, *p.* 241, *ed.* 4.)

Room being made for the reduction of the protruded parts into the abdomen by the division of the stricture, they are to be immediately returned, if sound and free from adhesions. This object is considerably facilitated by bending the thigh. The intestines are to be reduced before the omentum; but when a portion of mesentery is protruded, it is to be returned before either of the preceding parts. The intestine should always be reduced, unless it be found in a state of actual mortification. It often appears so altered in colour, that an uninformed person would deem it improper to return it into the abdomen. However, if such alteration should not amount to a real mortification, experience justifies the reduction of the part. Sir A. Cooper has judiciously cautioned the operator not to mistake the dark chocolate-brown discolorations for a state of gangrene. With these the protruded part is frequently found affected; and as they generally produce no permanent mischief, they ought to be carefully discriminated from the black-purple, or lead-coloured spots which usually precede mortification. To determine whether a discoloured portion of intestine be positively mortified, some recommend pressing forwards the blood contained in the veins; and if they fill again, it is looked upon as a proof that the bowel is still possessed of life.

In returning a piece of intestine into the abdomen, the surgeon should first introduce the part nearest the ring into this aperture, and hold it there till another portion has succeeded it. This method is to be continued till the whole of the protruded bowel is reduced.

The employment of force or violence in the endeavours to return the contents of a hernia in the operation, cannot be too severely reprobated; a method the more pernicious because such parts are more or less in a state of inflammation. It is always better to enlarge the stricture, than pinch and bruise the bowel in trying to get it through an opening which is too small. Distention of the intestine sometimes prevents the reduction; but when this is the only impediment, the part may generally be returned as soon as its contents have been compressed into the intestinal canal within the stricture. It is better, however, to dilate the strangulation a little more, than use any force in trying to get the intestine back into the abdomen in the manner just suggested.

Reduction is sometimes impeded by the protruded parts adhering to each other or to the hernial sac. The intestines are not often found very firmly adherent together. The omentum and inside of the sac are the parts which are most subject to become intimately connected by adhesions. The fingers will commonly serve for breaking any recent slight adhesions which may have taken place between the intestines and inside of the hernial sac. When those adhesions are firm, and of long standing, they must be cautiously divided with the knife; an object which can be most easily and safely accomplished, in case they are long enough to permit the intestine to be elevated a little way from the surface of the sac. But, provided their firmness and shortness keep the external coat of the bowel and inner surface of the sac in close contact, the greatest care is requisite in separating the parts with a knife, so as to avoid wounding the intestine. In doing this, the most prudent and safe method is not to cut too near the bowel, but rather to remove the adherent parts of the sac, and return them with the intestine into the abdomen. Every preternatural connexion should always be separated before the viscera are reduced: Sir A. Cooper mentions, that a fatal obstruction to the passage of the intestinal matter has arisen from the mere adhesion of the two sides of a fold of intestine together.—(*P.* 31.) When the adhesions which prevent reduction are situated about the neck of the sac, and out of the operator's view, it is best to make the wound through the skin and abdominal ring somewhat larger, so as to be able to separate the adhesions with more safety.

Having reduced the parts, the operator should introduce his finger, for the purpose of being sure that they are fairly and freely returned into the abdomen, and no longer suffer constriction, either from the inner opening, from the ring, or the parts just within the cavity of the peritoneum.

Sometimes a strangulated hernia is complicated with a hydrocele; a circumstance which may render it necessary either to cut through the latter swelling, or to limit the incision into the hernial sac, according as the hydrocele happens to cover the whole of the front of the sac, as seen by M. Cloquet and Mr. Stanley, or merely to advance in front of the lower part of the rupture.—(See *Lawrence on Ruptures*, *p.* 276, *edit.* 4.)

TREATMENT OF THE OMENTUM.

In an entero-epiplocele, this part, if healthy and free from gangrene, is to be reduced after the intestine. When, however, it is much diseased, thickened, and indurated, as it frequently is found to be, after remaining any considerable time in a hernial sac, the morbid part should be cut off. Its reduction in this circumstance would be highly improper, both because an immoderate enlargement of the wound would be necessary, in order to be able to put the diseased mass back into the abdomen, and because, when reduced, it would, in all probability, excite inflammation of the surrounding parts, and bring on dangerous symptoms.—(See *Hey*, *p.* 172.)

The diseased omentum should always be cut off with a knife; and if any of its arteries should bleed, they ought to be taken up with a tenaculum, and tied separately with a small ligature. An unreasonable apprehension of hemorrhage from the cut end of the omentum has led many operators to put a ligature all round this part, just above the diseased portion, which they were about to remove. This practice cannot be reprobated in terms too severe; for a frequent effect of it is to bring on a fatal inflammation, and even mortification of the omentum, extending within the abdomen, as high as the stomach and transverse arch of the colon. Sir Astley Cooper has remarked, with great truth, that it is surprising this custom should ever have prevailed. The very object of the operation is to extricate the omentum from its strangulated state, arising from the pressure of the surrounding tendon, and no sooner has this been done, than the surgeon includes it in a ligature, which produces a more perfect constriction than that which existed before the operation was undertaken.

"When the omentum has suffered strangulation for a few days (says Mr. Lawrence), it often becomes of a dark red or livid colour; and there is an appearance, on cutting it, as if some blood were extravasated in its substance. This, I believe, is the state which surgeons have generally described under the term of gangrene."—(*P.* 262.)

When cut in this state, it does not bleed. I need hardly observe, that the dead part must be amputated, and never reduced. Some have advised leaving the

omentum in the wound, especially in cases of old herniæ, in which it has been a long while protruded. Hey mentions cases, showing that granulations form very well, and that the wound becomes firmly healed, when this plan is followed.—(*P.* 180, *&c.*) Every one, however, will acknowledge the truth of what Mr. Lawrence says on this subject. The method "is attended with no particular advantage, but certainly exposes the patient to the possibility of ill consequences. The omentum, left in the wound, must be liable to injury, inflammation, or disease. Unnatural adhesions, formed by this part, have greatly impaired the functions of the stomach. Cases are recorded, where the unfortunate patient has never been able to take more than a certain quantity of food, without bringing on instant vomiting; and even where it has been necessary for all the meals to be taken in the recumbent position, with the trunk curved, and the thighs bent.—(*Gunz.*) To avoid the possibility of such afflicting consequences, we should, after removing any diseased portion, carefully replace the sound part of the omentum in the abdominal cavity."—(*On Ruptures*, *p.* 291, *ed.* 4.)

TREATMENT WHEN THE INTESTINE IN THE SAC IS MORTIFIED.

Sometimes, on opening the hernial sac, the intestine is found to be in a gangrenous state, although the occurrence could not be previously known, owing to the integuments and the hernial sac itself not being affected with the same mischief. In ordinary cases, however, both the skin and sac become gangrenous at the same time with the contents of the hernia. The tumour, which was previously tense and elastic, becomes soft, doughy, emphysematous, and of a purple colour. Sometimes the parts also now spontaneously return; but the patient generally survives only a few hours.

Sir A. Cooper has accurately remarked, that, in other instances, the skin, covering the swelling, sloughs to a considerable extent, the intestine gives way, and, as the feces find vent at the wound, the symptoms of strangulation soon subside. When the patient continues to live in these circumstances, the living part of the intestine becomes adherent to the hernial sac, the sloughs separate and come away, and thus an artificial anus is established, through which the feces are sometimes discharged, during the remainder of life. —(See *Anus*, *artificial*.)

Frequently, however, things take a more prosperous course; the feces gradually resume their former route to the rectum, and, in proportion as the artificial anus becomes unnecessary, it is shut up. Many instances of this sort have fallen under my own observation in St. Bartholomew's Hospital. The chance of a favourable event is much greater in some kinds of hernia than in others. When the strangulation only includes a part of the diameter of the gut, the feces are sometimes only partially discharged through the mortified opening. This quantity lessens as the wound heals, and the patient gets perfectly well.—(*Louis, Mém. de l'Acad. de Chir. t.* 3, *P. S. Palm. De Epiplo-enterocele crurali incarcerata sphacelata, cum deperditione notabili substantiæ intestini, sponte separati, feliciter curata alvo naturali restituta, &to. Tub.* 1748. *Haller, Disp. Chir. t.* 3.) A small gangrenous spot, or two, may end in the same manner. Mortification, as well as wounds, of the large intestines, is much more frequently followed by a recovery, than the same affection and similar injuries of the small intestines. Mortification of the cœcum and its appendix, in a hernial sac, has happened several times without materially disturbing the usual course of the feces to the anus, and the patients have soon recovered.—(*Med. Obs. and Inq. vol.* 3, *p.* 162. *Hey's Pract. Obs. p.* 162, *&c.*)

The grand thing on which the establishment of the continuous state of the intestinal canal depends, in all these cases, is the adhesion which the living portion of the bowel, adjoining the mortified part, contracts with the peritoneum all round. In this manner, the escape of the contents of the bowels into the cavity of the peritoneum becomes in general completely prevented. The two ends of the sound portion of intestine, after the mortified part has separated, open into a membranous cavity, which previously constituted a portion of the peritoneal sac, and now unites the extremities of the gut. The gradual contraction of the wound closes the membranous cavity externally, and thus the continuity of the canal is restored. The two ends, however, are not joined so as to form a continued cylindrical tube, like that of the natural gut: but they are united at an angle more or less acute, and the matter, which goes from one to the other, describes a half circle in a newly formed membranous cavity that completes the canal; a subject which has been more fully explained in another part of this work.—(See *Anus*, *artificial*.)

It is an observation of Sir A. Cooper's, that the degree of danger, attending an artificial anus, depends on the vicinity of the sphacelated part of the intestinal canal to the stomach. Thus, if the opening be in the jejunum, there is such a small extent of surface for absorption, between it and the stomach, that the patient dies of inanition.

Let us now suppose, that the mortified state of the intestine has only been discovered, after laying open the hernial sac in the operation. The mischief may only consist of one or more spots; or of the whole diameter of the protruded bowel. In the first case, the proper practice is to divide the stricture, and return the intestine into the abdomen, with the mortified spots towards the wound. Mild purgatives and clysters are then to be exhibited. The most favourable mode in which a case of this kind ends, is when the intestinal matter gradually resumes its natural course, after being either partly or entirely discharged from the wound. But sometimes the patient sinks under the disease, or an artificial anus continues for life.

The repeated observations of modern surgeons have now decided, that no ligature, passed through the mesentery, to keep the gangrenous part of the bowel near the wound, is at all necessary. The parts in the neighbourhood of the ring have all become adherent together, in consequence of inflammation, at the same time that the parts in the hernial sac mortified; and, of course, the partially gangrenous bowel, when reduced, is mechanically hindered, by these adhesions, from slipping far from the wound. Desault and De la Faye both confirm the fact, that the intestine never recedes far from the ring; and, even were it to do so, the adhesions, which it soon contracts to the adjacent surfaces, would, as Petit has explained, completely circumscribe any matter which might be effused, and hinder it from being extensively extravasated among the convolutions of the viscera.—(*Mém. de l'Acad. de Chir. t.* 1, 2.)

Where the chief part, or the whole, of the diameter of the protruded bowel is mortified, the first and most urgent indication is to relieve the bad symptoms arising from the distention of the intestinal canal above the stricture. "Let a free incision (says Mr. Lawrence) be made through the mortified part of the gut, in order to procure that evacuation of the loaded canal, which nature attempts by the process of gangrene." If the intestine has already given way, a free division of the integuments and sac allows the exit of the accumulated matter; and the opening in the gut may be enlarged, if necessary.—(*On Ruptures*, *p.* 299, *ed.* 4.) By such treatment, Sir Astley Cooper rescued from the grave a female who was pregnant at the time of the operation, and was some months afterward safely brought to bed.—(See *Lancet*, *vol.* 2, *p.* 143.)

Here the division of the stricture is unnecessary, since all the mischief, which the bowel can receive from it, is done. This subject is well explained by Mr. Travers.—(See *Inq. into the Process of Nature in repairing Injuries of the Intestines*, *&c. p.* 300, *&c.*) Mild purgatives and clysters will be proper to unload the bowels, and determine the course of the feces towards the anus. Should, however, the stricture appear after the mortification to impede the free escape of the intestinal contents, a moderate dilatation of it must undoubtedly be proper.

Mr. Lawrence has clearly exposed the impropriety of sewing the ends of the intestinal canal together, introducing one within the other, supported by a cylinder of isinglass, &c. put into their cavity, in those cases in which the whole circle of the intestine has mortified, and been cut away, as was advised by former writers. By drawing the intestine out of the cavity, in order to remove the dead part, the adhesions behind the ring, on which the prospect of a cure chiefly depends, must be entirely destroyed; and new irritation and inflammation must be unavoidably produced, by handling and sewing an inflamed part. The adhesions would even be likely to render the scheme impracticable, as

happened in a case related in the *Journ. de M. Le Roux, t.* 21, *p.* 260.—(*On Ruptures, p.* 314, *ed.* 4.)

Instead of such practice, Mr. Lawrence judiciously recommends dilating the stricture, and leaving the subsequent progress of the cure entirely to nature. The sloughs will be cast off, and the ends of the gut are retained by the adhesive process in a state of apposition to each other, the most favourable for their union. Thus, there is a chance of the continuity of the intestinal canal becoming established again.

Whatever experiments it may be allowable to make in wounds with protrusion and division of the bowels, nothing, I think, is now more completely established, than the absurdity and danger of attempting to stitch the bowels in cases of hernia.

OPERATION FOR VERY LARGE INGUINAL HERNIÆ.

When the tumour is of long standing, exceedingly large, perhaps extending half way down to the knees, and its contents have never admitted of being completely reduced, the indication is to divide the stricture, provided a strangulation take place; but without laying open the hernial sac, or attempting to reduce the parts.

The reasons against the common plan of operating, under such circumstances, are, the difficulty of separating all the old adhesions; the hazardous inflammation which would be excited by laying open so vast a tumour; and the probability that parts, so long protruded, might even bring on serious complaints, if reduced. J. L. Petit, and afterward Dr. Monro, advised the sac not to be opened.—(See *Mal. Chir. t.* 2, *p.* 372. *Description of Bursæ Mucosæ*, 1788.) Mr. Lawrence recommends an incision, of two or three inches in length, to be made through the integuments over the abdominal ring. The fascia, covering the hernial sac, is then to be exposed by dissection, and an opening made in it. This will permit a grooved direction to be put under the tendon; and the probe-pointed bistoury may be conducted, by means of the groove, to the part that requires division. If great difficulty should be experienced in accomplishing our object in this manner, a small aperture may be made in the sac near the ring, when the tendon may be divided with ease. The parts, after being thus liberated, should be returned into the belly, by pressure on the swelling, if adhesions do not prevent it: at all events, they generally admit of being replaced in part.—(*Lawrence on Ruptures, p.* 269, *ed.* 4.) A very interesting case has been recorded, in which the foregoing advice was deviated from, and a large scrotal hernia laid open; when it was found that nearly a foot of the colon was contained in the swelling, and could not be reduced. The integuments could not cover it; yet its surface granulated, the skin extended itself as the cicatrix contracted over the swelling, which also diminished, and, in about six weeks the cure was completed.—(See *Journ. of Foreign Med. No.* 15, *p.* 460.)

OPERATION WHEN THE HERNIA IS SO SMALL THAT IT DOES NOT PROTRUDE EXTERNALLY THROUGH THE RING.

In this kind of case, there is little appearance of external tumour; consequently, the disease is very apt to be overlooked by the patient and surgeon, and some other cause assigned for the series of symptoms. The manner of operating, in this form of the disease, differs from that in the common scrotal hernia: the incision is to be made in the direction of the spermatic cord, and the stricture will be found at the internal ring.—(*A. Cooper on Inguinal Hernia.*)

TREATMENT AFTER THE OPERATION.

Evacuations from the bowels should be immediately promoted by means of clysters, oleum ricini, or small doses of sulphate of magnesia, dissolved in peppermint water; but the patient should not be allowed to quit the recumbent position, or get on the night-stool, as doing so is apt to bring on a protrusion of the bowels again.—(See case in *Lancet, vol.* 2, *p.* 148.) The safest plan is to let something be put under him for the reception of the feces. In the course of another day, if costiveness follow the effects of the first medicines, and tenderness and tension of the belly come on, local and general bleeding, with the exhibition of liberal doses of calomel joined with opium are strongly indicated. For some time the diet is to be low. When symptoms of inflammation of the bowels and peritoneum threaten the patient, general bleeding, leeches on the abdomen, fomentations, blisters, doses of the oleum ricini, and clysters, are the means deserving of most dependence, and should be resorted to without the least delay. In these circumstances, the warm bath, sometimes recommended, I think is more likely to do harm than good, by the disturbance to which it subjects the patient. When all danger of peritoneal inflammation is past, and the patient is very low and weak, bark, wine, cordials, and a generous diet must be directed. The effervescing saline draught, with opium, is the best medicine for quieting the disturbance of the stomach after the operation. Opium and cordials are the most eligible for checking diarrhœa. As the operation does not usually prevent the parts from becoming protruded again, a truss must be applied before the patient leaves his bed, and afterward constantly worn.

PROPOSALS FOR THE RADICAL CURE OF THE BUBONOCELE.

Of castrating the patient, applying caustic, or of the operation of the punctum aureum, with this view, I need only say that they are barbarous, and not at all calculated for the attainment of the desired end. A description of these methods may be found in Paré, Wiseman, &c.

The old operation termed the *royal stitch* was one of the most promising plans. It consisted in putting a ligature under the neck of the hernial sac close to the abdominal ring, and then tying that part of the sac, so as to render it impervious by the adhesive inflammation thus excited.

The royal stitch performed in this manner, has been actually attended with success.—(*Heister, vol.* 2.) The umbilical rupture was cured by Saviard, on similar principles; and Desault radically cured nine cases of the exomphalos in children by tying the hernial sac.

Schmucker cured two irreducible ruptures, free from strangulation, by cutting away the body of the sac after tying its neck.—(*Chir. Wahrnehmungen, b.* 2.) In one case, Sir A. Cooper found cutting away the sac alone insufficient.

Dissecting away the whole hernial sac, or even laying it open, must be a formidable operation, compared with merely making a small incision down to the neck of the sac and applying one ligature. If the hernia were reducible, and the upper part of the sac could be rendered impervious by the ligature, all other more severe plans would be superfluous. However, Petit, Sharp, Acrel, &c. record cases which tend to prove the danger and inefficacy of the royal stitch; though it is true that none of these surgeons operated exactly in the simple manner above suggested.

Richter recommends scarifying the neck of the sac, with the view of producing an adhesion of its sides to each other; a plan which he says he found very successful.

From the account, however, which has been given of the anatomy of the bubonocele, it is obvious that none of these methods could do more than obliterate the sac as high as the ring, and never that portion of it which is within the inguinal canal. Hence, the neck of the sac must still remain open for the descent of the viscera. This consideration, and that of the chances of bad and fatal symptoms from any operation undertaken solely for this purpose, and not urgently required for the relief of strangulation, are the grounds on which these experiments are now disapproved.

CRURAL OR FEMORAL HERNIA.

Verheyen, who wrote in 1710, first distinctly pointed out the nature of crural hernia, which, until then, had been generally confounded with bubonocele.

The parts composing this kind of hernia always protrude under Poupart's ligament, and the swelling is situated towards the inner part of the bend of the thigh. The rupture descends on the inside of the femoral artery and vein, between these vessels and the os pubis, through the *crural ring*, or *canal* for the transmission of the same vessels. And, as Hesselbach has remarked, the inner opening of this ring or canal is the predisposing cause of the disease, the peritoneum spread over it being gradually propelled into it by various occasional causes, so as to complete the tendency to hernia. The actual protrusion of the bowels may be formed either suddenly or by degrees. As soon as the bowels have

once passed the outer aperture, or what Cloquet terms more properly the lower opening of the crural canal, the hernia has more room for extending itself forwards, and to each side, and the integuments now become elevated into *an oval swelling, the long diameter of which is nearly transverse.*—(*Hesselbach, p.* 47.) Gimbernat names the passage through which the femoral hernia protrudes from the abdomen, the *crural;* Hey, the *femoral ring;* and Cloquet, the *crural canal.*

Females are particularly subject to this kind of rupture. It has been computed, that nineteen out of twenty married women afflicted with hernia have this kind; but, that not one out of a hundred unmarried females, or out of the same number of men have this form of the disease.—(*Arnaud.*)

"The crural hernia," says Scarpa, "is frequently observed in women who have had several children; it very seldom afflicts young girls; and still more rarely men. In the latter, the viscera can more easily escape through the inguinal ring by following the spermatic cord, than they can descend along the crural vessels, and raise the margin of the aponeurosis of the external oblique muscle that forms the crural arch. In women, an opposite disposition prevails, in consequence of the smallness of the inguinal ring, which in them, only gives passage to the round ligament of the uterus, and besides is situated lower down and nearer the pubes than it is in men, while, on the contrary, the crural arch is more extensive by reason of the wider form of the pelvis. Morgagni expressly says, that he never met with the crural hernia in the dead body of any male subject. *Mihi, ut verum fatear, nisi nondum in fœminis accidit ut eam viderem.*—(*De Sed. et Caus. Morb. epist.* 34, 15.) Camper gives us to understand almost the same thing.—(*Icones Herniarum, in Præfat.*) Hévin often operated for this kind of hernia in females, but only once in the male subject.—(*Fathol. et Therap. p.* 406.) Sandifort and Walter have both seen but a single instance of it in the dead body of the male subject. —(*Obs. Anat. Pathol. cap.* 4, *p.* 72. *Sylloge Comment. Anat. p.* 24, *obs.* 21.) Arnaud himself, to whom modern surgery is highly indebted for many important precepts on the operation for the strangulated crural hernia in both sexes, candidly confesses that he had never had an opportunity of dissecting a hernia of this kind in the male subject."—(*Scarpa, Traité des Hernies, p.* 201.)

Scarpa had at his disposal a male subject in which there was a crural hernia, and he availed himself of the opportunity of examining the parts with the utmost care. He first injected the blood-vessels; he afterward attentively dissected all the parts concerned in the disease; and he has published an exact description of the particulars, illustrated by an engraving.

According to Hesselbach, the femoral hernia, though not common in men, is more frequent than is generally believed, and often overlooked on account of its being very small.—(*Ueber den Ursprung, &c. der Leisten-und-Schenkelbrüche, p.* 47.) Thus, in an example published in a modern work, an inguinal and femoral hernia were met with together in a gentleman sixty-three years of age. On examination of the body after death, a small piece of intestine forming a crural hernia was found strangulated and concealed under an inguinal rupture and a mass of fat.—(*C. Bell's Surgical Obs. vol.* 1, *p.* 187.)

Mr. Lawrence states that the femoral rupture is not so uncommon in men as several authors would lead us to suppose. He has seen many instances of it.—(*On Ruptures, p.* 409, *note, ed.* 4.) Dr. Breschet, it seems, has also seen as many as thirty examples of it in the practice of Dupuytren.—(*Consid. et Obs. Anat. &c. sur la Hernie Fem.* in his *Concours, p.* 42.)

According to the observations of Scarpa, and all the best modern writers upon surgery, the crural hernia forms both in the male and female subject, in the cellular substance, which accompanies the crural vessels below Poupart's ligament. The swelling follows the internal side of those vessels and gradually descends into the fold of the thigh, between the sartorius, gracilis, and pectineus muscles. "Many surgeons believe (says Scarpa) that the hernial sac, and the intestines which it contains, are ordinarily situated above the crural vessels and the trunk of the vena saphena, and sometimes between these vessels and the anterior superior spine of the ilium. But as far as my knowledge extends, this assertion is not supported by a single accurate description of the crural hernia in the early stage. It is true, that when the tumour has in time acquired a large size, and its fundus is inclined in a parallel manner to the fold of the thigh, it partly or entirely covers the crural vessels, and even the crural nerve, as Walter says he once observed.—(*Sylloge Comment. Anat. p.* 24.) But, it is not thence to be concluded, that the tumour in the beginning descended over the crural vessels, much less between them and the anterior superior spinous process of the ilium. Neither must it be imagined that the neck of the hernial sac becomes removed from the inner to the outer side of these vessels. If these two cases ever happen, they must be very rare; and the best authors who have treated of crural hernia concur in stating that in performing the operation, they have constantly found the viscera situated on the inside of the crural vessels, but never on their outside. Even when the tumour, after acquiring a considerable size, is situated transversely over the crural vessels, the neck of the hernial sac has always been found upon their inner side, that is to say, between them and the pubes. Le Dran (*Observ. de Chir. t.* 2, *p.* 2), La Faye (*Cours d' Opérations de Dionis, p.* 358), Petit (*Œuvres Posthumes, t.* 2, *p.* 219), Morgagni (*De Sed. et Caus. Morb. epist.* 34. 15), Arnaud (*Mém. de Chir. tom.* 2, *p.* 768), Gunz (*De Herniis Libellus, p.* 78), Bertrandi (*Trattato delle Operazioni, t.* 1, *Annot. p.* 218), Pott (*Chirurg. Works, vol.* 2, *p.* 152), Desault (*Traité des Mal. Chirurg. p.* 191—195), *B. Bell* (*A System of Surgery, vol.* 1, *p.* 387), Richter (*Traité des Hernies, chap.* 34), Nessi (*Instituz. Chir. t.* 2, *p.* 198), Lassus (*Méd. Opér. t.* 1, *p.* 198), and many other writers all concur upon this point. "In support of their opinion (says Scarpa), I could cite a great number of cases of my own, which I have collected either in operating on several individuals for crural hernia, or in dissecting the same kind of hernia in the bodies of many female subjects, and in that of the man from whom I have taken the 8th plate. Lastly, also, having had an opportunity of dissecting in a female an enormous crural hernia, which descended one third of the way down the thigh, I observed that the neck of the sac did not encroach at all upon the crural vessels, but lay entirely on their inner side."—(*Scarpa, Traité des Hernies, p.* 203. 206.)

The tumour, on account of its situation, is liable to be mistaken for an enlarged inguinal gland; and many fatal events are recorded to have happened from the surgeon's ignorance of the existence of the disease. Mr. Lawrence once saw a hospital surgeon mistake a crural hernia for a glandular tumour, and the patient died, without any attempt being made to afford relief by the operation.—(*P.* 413, *ed.* 4.) See also Petit, (*Traité des Mal. Chir. t.* 2, *p.* 293, *&c.*) A gland can only become enlarged by the gradual effects of inflammation; the swelling of a crural hernia comes on in a momentary and sudden manner, and, when strangulated, occasions the train of symptoms already described in our account of the inguinal hernia, which symptoms an enlarged gland could never occasion. Such circumstances seem to be sufficiently discriminative; though the feel of the two kinds of swelling is often not of itself enough to make the surgeon decided in his opinion. It is particularly remarked by Hesselbach, that while a femoral hernia is incomplete, that is to say, within the outer opening of the passage, through which the parts descend, the disease presents itself as a round, firm swelling, on the outer side of which the femoral artery can be felt pulsating: this small hernia may be mistaken for an inflamed gland, and the case can only be discriminated by the history of its origin and symptoms.—(*Ueber den Ursprung der Leisten-und-Schenkelbrüche, p.* 51.) A femoral hernia may be mistaken for a bubonocele, when the expanded part of the swelling lies over Poupart's ligament. As the taxis and operation for the first case ought to be done differently from those for the latter, the error may lead to very bad consequences. *The femoral hernia, however, may always be discriminated, by the neck of the tumour having Poupart's ligament above it. In the bubonocele, the spine of the pubes is behind and below this part of the sac; but in the femoral hernia, it is on the same horizontal level, and a little on the inside of it.* —(See *Lawrence on Ruptures, p.* 414, *ed.* 4.)

In the male subject, "the crural hernia, in the early stage (says Scarpa), is situated so deeply in the bend of the thigh, that it is difficult, even in the thinnest persons, to feel its neck; and in examining its circum-

ference with the extremity of the finger, the tendinous margin of the opening, through which the parts are protruded, can only be perceived with considerable difficulty. On the contrary, the inguinal hernia, however small it may be, is always less deeply situated; it is about half an inch above the bend of the thigh. In carrying the finger round its neck, the tendinous margin of the inguinal ring can be easily felt at its circumference; and at the posterior part of the small tumour, the cord composed of the spermatic vessels is distinguishable. *When the crural hernia has acquired a considerable size, its neck is always deeply situated in the bend of the thigh; but its body and fundus assume an oval form, and their great diameter is situated transversely in the bend of the thigh.* Whatever may be the size of the inguinal hernia, it always presents a tumour of a pyramidal form, the base or fundus of which, far from being directed towards the ilium, follows exactly the direction of the spermatic cord, and descends directly into the scrotum. Besides the symptoms common to all hernial swellings, the crural hernia, when it has attained a certain size, presents some others which are peculiar to it, such as *a sense of stupor and heaviness in the thigh*, and *œdema of the leg, and even of the foot*, of the same side." The reason why œdema and numbness of the limb are particularly remarkable in cases of femoral hernia, is justly referred by Hesselbach to the circumstance of the femoral vessels and nerves, with numerous lymphatics, taking their course through the crural ring; and, according to his observations, the numbness and œdema are especially great when the protrusion is omentum, which makes stronger pressure on the vessels and nerves than commonly happens in a case of enterocele. —(*P.* 53.)

"In women, however (as Scarpa observes), it is less easy to distinguish the crural hernia from the inguinal. In fact, the absence of the spermatic cord, and the nearer situation of the ring to the crural arch, may easily occasion a mistake. Sometimes, a woman may even be supposed to have a double crural hernia of the same side, while, of these two distinct, though neighbouring herniæ, one may be inguinal, and the other crural. Arnaud (*Mém. de Chir. t.* 2, *p.* 605) relates an instance of such a mistake."—(*Scarpa, Traité des Hernies, p.* 207, 208.)

This interesting writer takes occasion to observe further, upon this part of the subject, that the portion of the inferior pillar of the abdominal ring, which separates this opening from the internal and inferior angle of the crural arch, is so slender in women, that it is sometimes hard to distinguish the crural from the inguinal hernia, which is not the case in male patients.

Until a few years ago, the stricture, in cases of femoral hernia, was always supposed to be produced by the lower border of the external oblique muscle, or, as it is termed, Poupart's ligament. A total change of opinion on this subject, however, has latterly taken place, in consequence of the observations first made by Gimbernat, in 1793. "In the crural hernia (says he), the aperture through which the parts issue is *not* formed by two bands (as in the inguinal hernia), but it is a foramen almost round, proceeding from the internal margin of the crural arch (Poupart's ligament), near its insertion into the branch of the os pubis, between this bone and the iliac vein: so that, in this hernia, the branch of the os pubis is situated more internally than the intestine, and a little behind; the vein, externally, and behind; and the internal border of the arch, before. Now, it is this border which always forms the strangulation."—(See *A New Method of operating for the Femoral Hernia.*)

The utility of knowing that it is not Poupart's ligament which produces the strangulation in cases of femoral hernia, is important; for we then know, that cutting the lower and outer border of the external oblique muscle is quite erroneous. This proceeding is the more to be reprobated, because the lower pillar of the abdominal ring, in both sexes, will be divided by directing the incision upwards, or upwards and inwards; and thus the abdominal and crural rings will be made into one common aperture, large enough to make the future occurrence of hernia very likely to happen. In the male there is also considerable danger of the spermatic cord being cut. Cutting Poupart's ligament obliquely outwards is attended with still more danger; for the epigastric artery will infallibly be divided at its origin; and with all these hazards, the incision must be quite useless, unless carried on to the internal edge of the crural arch.—(*Gimbernat, p.* 16.)

The inclination, however, of several modern writers to refer the strangulation entirely to Gimbernat's ligament is not sanctioned by the most careful observers, like Hesselbach and Langenbeck.—(*Neue. Bibl. b.* 2, *p.* 132.) The former justly remarks, that a complete femoral hernia may be strangulated in two places, either at the outer or inner opening of the passage through which the protrusion happens. Nay, says he, that the strangulation is sometimes caused by the outer opening was known to former surgeons, for they remarked that the constriction was removed by dividing the fascia.—(*P.* 53.) And, in addition to these two modes of strangulation, is to be enumerated a third, in which the viscera are constricted by protruding through some weaker point, or accidental opening, in the anterior parietes of the crural canal;—(*Hesselbach, p.* 48; *Cloquet, Recherches Anat. p.* 85; also, *Langenbeck, op. cit. p.* 132), or even through an aperture in the inner side of this passage, as we find depicted in the twentieth plate of Langenbeck's treatise, "De Structurâ Peritonæi."

I know of no surgical writer who has given a clearer account of the anatomy of the femoral hernia than Langenbeck.—(*Neue Bibl. b.* 2, *p.* 112, *&c.*) He observes, that when the dissection is begun at the inside of the inguinal region, the following circumstances are noticed: after the removal of the peritoneum from the abdominal muscles, and from the psoas, iliacus internus, and the great vessels, the inner surface of the transversalis still has an investment, which Cloquet terms the *fascia transversalis*, and which is always a white glistening aponeurosis. From the place where the femoral artery lies under Poupart's ligament, to the anterior superior spine of the ilium, the preceding fascia is extended in a strong fibrous form behind the inner surface of Poupart's ligament, and a thin continuation of it is extended over the iliacus internus and psoas muscles, where it is named by Sir A. Cooper and Cloquet the *fascia iliaca*. The fascia of the transverse muscle closes the belly behind Poupart's ligament, as completely as the peritoneum does, so that between the femoral artery and the anterior superior spine of the ilium none of the bowels can protrude, which occurrence is still further prevented by the fascia lata, which, below Poupart's ligament, is closely attached to the muscles of the thigh. By the pelvis being thus shut up, the origin of a crural hernia on the outside of the femoral vessels is rendered quite impossible.—(*Langenbeck, op. cit.*) This part of the explanation very nearly resembles that delivered by Sir A. Cooper, except that the latter describes the iliac fascia, and not what Cloquet calls the transverse fascia, as closing the pelvis from the spine of the ilium to the crural vessels. But this difference is easily accounted for by the circumstance of Sir A. Cooper extending the name fascia iliaca beyond the limits given it by Cloquet and Langenbeck.

Near the anterior superior spinous process of the ilium, Langenbeck remarks, that the fascia of the transverse muscle has some strong fibres, which proceed inwards under the internal opening of the inguinal canal, of which they form, as it were, the bottom, and are named by Hesselbach the *internal inguinal ligament*. They go over the femoral artery and vein, are connected above with the fascia of the transverse muscle, and below are continued into the fascia of the psoas and iliac muscles. Where these fibres pass over the femoral vessels, they expand into a firm aponeurosis, which, passing downwards, is intimately attached at the inner side of the femoral vein to the horizontal branch of the os pubis, close to the symphysis, and then joins the aponeurosis of the recti muscles. The expanded portion of the foregoing tendinous fibres, thus continued along the crista of the os pubis to the sheath of the rectus, forms the inner surface of *Gimbernat's*, or the *femoral*, or *crural ligament*. The inner edge of this ligament is falciform and concave, the concavity being turned towards the femoral vein. Now, where the fascia of the transverse muscle extends downwards on the outer side of the crural artery, to the fascia of the psoas and iliac muscles, so as to close the pelvis between that vessel and the anterior superior spinous process of the ilium, it also forms, like Gimbernat's ligament, a falciform edge, the concavity of

which lies close over the external convexity of the crural artery. Thus, partly by the concave edge of Gimbernat's ligament, directed towards the crural vein, and partly by the concave edge of the extension of the fascia of the transverse muscle to the fascia iliaca, which edge is turned towards the crural artery, an aperture is produced, through which the femoral vessels pass out of the pelvis. This opening is named by Cloquet the *upper opening of the crural canal*, or, as many English surgeons would say, of the *crural* or *femoral ring*. By Hesselbach, it is called the *internal opening for the femoral vessels*. However, as these vessels do not lie loosely and unconnectedly in this aperture, the opening itself is shut up, as it were, and cannot be seen without dissection.

On the above-described fasciæ there is a considerable quantity of cellular substance, which covers the vessels in the pelvis, forms a sort of sheath for the crural artery and vein, and accompanies these vessels through the inner opening of the crural canal, or ring, which is itself accurately shut up by it. When this cellular substance is removed, the white glistening fasciæ are plainly seen passing through the same opening, and coming nearer together in a funnel-like manner. Where the fascia of the transverse muscle forms the outer falciform edge of this aperture, and is passing over the arteria circumflexa ilii to the psoas and iliac muscles, it sends off through the opening a process, which becomes connected with the outer side of the crural canal or ring; while from the internal inguinal ligament, which lies above this opening, and constitutes the upper edge of the inner aperture of the crural canal, a production is sent, which is connected with the anterior side of this canal. As for the posterior and inner sides, they have a connexion with the fasciæ of the psoas and levator ani.

When the groin is externally dissected, in order to have a view of the crural ring or canal, on the outside of the pelvis, the following appearances present themselves: after the removal of the common integuments, one finds below Poupart's ligament a quantity of fat, glands, lymphatics, veins, and arteries, which vessels come out through small openings in the fascia lata. As soon as the outer surface of the external oblique muscle is cleared, its aponeurosis is found to become stronger at the anterior superior spinous process of the ilium, and its fibres to collect together, and assume the form of a band, which is Poupart's ligament, called by Hesselbach the *external inguinal ligament*, and by Gimbernat, Cloquet, and others, the *crural arch*. This ligament, as is well known, passes obliquely, inwards and downwards, towards the os pubis, and, after forming the external pillar of the abdominal ring, is first closely inserted into the angle or tubercle of the os pubis, and then being continued inwards, or backwards, in the form of a firm fascia, is attached to the horizontal ramus of that bone, making the *anterior or outer surface of Gimbernat's, or the femoral ligament*, which is consequently produced by the junction of Poupart's with Hesselbach's internal inguinal ligament along the spine of the os pubis. Thus, just as the internal inguinal ligament is a strengthened part of the fascia of the transverse muscle, the outer inguinal ligament (or, as it is here commonly called, Poupart's ligament), is produced by the strengthened fibres of the lower portion of the aponeurosis of the external oblique muscle, the fibres of it, making the external pillar of the ring, being continued further towards the symphysis of the pubes, in the form of the outer surface of Gimbernat's ligament.—(*Langenbeck, Neue Bibl. b.* 2, *p.* 120, 121.) English surgeons make the formation of Gimbernat's or the femoral ligament more simple: thus, Mr. Lawrence states, that when Poupart's ligament approaches the pubes, "it becomes suddenly broader; that it is fixed by this broad portion, along the whole length of the angle and crista of the pubes; that it has a rounded and strong anterior edge, a thin and sharp posterior margin; and that the former of these is nearer to the surface, while the latter is comparatively deeply seated. The breadth of this part varies in different subjects; it is generally from three quarters of an inch to an inch. Sometimes, as Gimbernat has stated, it measures more than an inch. Dr. Monro has observed, that it is broader in the male than in the female subject; and from this structure he explains in part the more rare occurrence of this rupture in the male."—(*P.* 368, *ed* 3)

The fascia lata, which is spread over the muscles of the thigh, is only a continuation of the aponeurosis of the external oblique muscle, and, as it proceeds downwards from Poupart's ligament, is very closely attached to the muscles of the thigh, all the way from the anterior superior spinous process of the ilium, to the femoral artery, drawing, as it were, Poupart's ligament downwards and inwards, or backwards, towards the cavity of the pelvis, so as to give to its external edge a convex appearance, and shut up the outside of the pelvis, from the anterior superior spine of the ilium as far as the crural nerve and artery, so firmly, that the formation of a femoral hernia at this part is impossible. And if small apertures filled with fat be discernible in this portion of the fascia lata, still no hernia can here take place, because, as Langenbeck has already explained, here the interior of the pelvis is again shut up by fasciæ already described.

Under the fascia lata are situated the anterior crural nerve, the vein, and artery. The vena saphena magna lies on the outside of it, and passes through an opening in it into the femoral vein. This aperture in the fascia lata is at the inner side of the groin, opposite the internal opening of the crural ring or canal. It is named by Hesselbach *the external aperture for the femoral vessels*, and described by him as an oblique fissure about fifteen lines in length. He takes notice of its external semilunar edge and two horns which are directed inwards; the parts first particularly described by Mr. A. Burns of Glasgow, under the name of the *semilunar*, or *falciform process of the fascia lata*. The lower horn bends rather inwards and upwards, and terminates in the production of the fascia lata spread over the pectinalis muscle. The upper horn, which is less curved, buries itself under the external pillar of the abdominal ring. Over the lower horn of the opening, just now described, the vena saphena magna ascends into the femoral vein. Through the same aperture also pass nearly all the superficial lymphatics of the lower extremity. According to Cloquet, the fascia lata consists of two layers, of which the anterior superficial one is closely attached to the crural arch, extends over the femoral vessels, and forms the anterior side of the crural canal. The other layer, near the pubes, quits the former, and covering the pectinalis muscle, constitutes the hinder side of that canal. The anterior layer of the fascia then forms an oval aperture, through which the vena saphena passes, and which is considered by Cloquet as *the lower opening of the crural canal*. This opening, called by Hesselbach *the external foramen for the femoral vessels*, is well delineated both in his excellent work, and in the twenty-third plate of Langenbeck's book.—(*De Structurâ Peritonæi, Testiculorum Tunicus, &c.* 8vo. *Gött.* 1817.) According to the investigations of the last anatomists, as soon as the integuments are removed, this opening in the fascia lata, with its external semilunar edge, and two horns, are regularly seen. The front side of the crural canal is formed by the fascia lata. Where this fascia proceeds in the form of Hesselbach's upper horn under and behind the external pillar of the abdominal ring, and makes the outer layer of Gimbernat's ligament, it is continued as a thin aponeurosis over the vena saphena, so that it makes not merely the upper horn, but reaches further downwards and forms the outer side of the crural canal. The outer side then of the crural canal or ring, according to Langenbeck, extends from the outer semilunar edge of the external opening for the femoral vessels, or, as English surgeons would say, from the edge of the *falciform process of the fascia lata*. The larger the preceding thin continuation of fascia is, the smaller is the external opening for the femoral vessels, the more is the upper horn bent downwards, and the more determinate is the form of the canal.—(*Langenbeck, Neue Bibl. b.* 2, *p.* 124, 125.)

According to Mr. Lawrence, "At the upper and anterior part of the limb, the fascia lata consists of two portions, an external and an internal, with distinct insertions. The former, which is the thickest and strongest, covers the sartorius and rectus femoris, and is inserted into Poupart's ligament, from the anterior superior spine of the ilium to the inner edge of the femoral vein. The latter, thinner and weaker, covers the pectineus and adductor muscles, and is inserted into the pubes, in front of the origin of the former. It passes behind the femoral vessels, and is there con-

dnuous with the iliac fascia, while the external portion covers these vessels anteriorly, just below the crural arch, and the vessels themselves are consequently situated between these two divisions of the fascia."—(*On Ruptures*, *p.* 391, *ed.* 4.)

Where the insertion of the fascia lata into Poupart's ligament ends, it forms what Mr. Burns of Glasgow calls the *falciform process*, the upper part of which is attached to the above ligament, while the lower proceeds further down the thigh. The concavity of the falciform process is directed towards the pubes. This anatomical connexion is one chief cause why extending the thigh, and rotating it outward, render the crural arch tense.

The hernia being situated in front of the pectineus, must of course be exterior to the fascia lata. In my opinion, surgeons are very much indebted to Mr. Lawrence for his able explanation of this fact. As for myself I am candid enough to own, that until I read his clear and concise account of the anatomy of the crural hernia, I could never reap any accurate notions concerning the relative situations of the hernial sac and fascia of the thigh, from other more prolix works, with the exception of those of Hesselbach and Langenbeck, by whom the anatomy is made perfectly intelligible. Mr. Lawrence reminds us, however, that the particular crural hernia, contained in the sheath of the femoral vessels, lies under the fascia; *p.* 403, *edit.* 4. And he mentions, that "the upper end of the falciform process passes over the upper and outer part of the neck of the tumour; it is then folded under the crural arch, and continues into the thin posterior border. The iliac vein is placed on its outer side; the pubes is directly behind it; and the upper and inner parts are bounded by the thin posterior edge of Poupart's ligament. It is this part which forms the strangulation."—(*On Ruptures*, *p.* 404, *edit.* 4.) While, however, the latter statement is made by this gentleman and others, Sir Astley Cooper as positively declares, that the stricture is never situated at Gimbernat's ligament, but at the crural arch, just where the viscera leave the abdomen.—(See *Lancet*, *vol.* 2, *p.* 182.) He also mentions, that he has known the stricture continue after the division of that ligament, and the patient die. The more comprehensive view of this part of the subject taken by Hesselbach and Langenbeck, I have already explained.

The inner side of the crural ring or canal, as already explained, is connected with the fascia of the transverse muscle. And, according to Langenbeck, below the part of the fascia lata, which forms the external foramen for the femoral vessels, the front side of the crural canal is sometimes formed by a continuation of the fascia of the transverse muscle, as he found was the case in both groins of one female subject. In such a case there is a good deal of fat between the fascia lata and the aponeurosis of the transverse muscle, and the two parts are easily separable. Langenbeck admits, however, that the same appearance may arise from a splitting of the layers of the fascia lata. Frequently the front side of the crural ring is so short, that the opening cannot rightly be termed a canal, and it is always shorter than the posterior side. When the outer side exists, it is extended across the inner, over the space between the two horns, and is then connected with the aponeurosis of the pectinalis derived from the fascia of the psoas and levator ani muscles. In the anterior and inner sides of the crural canal, there are some small openings. Doubtless, this structure is referred to by Hesselbach, when he says, that in the male subject the outer openings for the femoral vessels is further closed by a net-like web of tendinous fasciculi. The posterior side of the crural canal, or ring, is entirely formed by the part of the fascia of the psoas, which enters its inner opening and joins the aponeurosis of the pectinalis muscle. The outer side of the canal lies under the fascia lata, and joins the anterior and posterior sides, where the aponeurosis of the transverse and iliac muscles proceed to the outside of the femoral artery. Langenbeck thinks the opening by which the vena saphena passes over the lower horn of the falciform process of the fascia lata, might be named *the lower aperture of the crural canal*.—(See *Langenbeck's Neue Bibl. für die Chirurgie*, *b.* 2, *p.* 126, 127, 8*vo*. *Hanover*, 1899.)

According to Hesselbach, in femoral hernia, the two openings of the passage now termed the crural or femoral ring are one-half larger than natural. The outer portion of the inner of these apertures is propelled more outward, and with it the epigastric artery. The femoral vein no longer lies at the external end of this opening, but rather at the back of the canal or passage. The external semilunar edge (the falciform process) of the outer opening is carried more outwards and upwards, and is tightly applied over the distended hernial sac. In this state of the parts, the outer opening forms an oval firm tendinous ring, the direction of which, like that of the inner opening for the passage of the femoral vessels, is transverse. The neck of the hernial sac is that portion of it which lies within the canal between the two openings. The posterior side of this canal or passage, now frequently named the crural or femoral ring, is longer than the anterior. In one large hernia, Hesselbach found it an inch and a half in length, but the anterior side of the passage more than one-third shorter. The greatest diameter of the inner opening was one inch, five lines, while that of the outer one was only one inch, four lines. Most of the posterior part of the neck of the hernial sac, with the hinder side of the canal, lies upon the pectineus muscle, and towards the outer side upon the femoral vein. The neck of the hernial sac adheres more firmly to the anterior than to the posterior side of the passage. At the outer opening of the passage, the neck terminates at almost a right angle forwards in the body of the sac, the upper portion of which lies upon Poupart's ligament; but the largest part of it is situated on the deep-seated layer of the femoral fascia, by which the outer side of the body of the sac, as high as the neck, is separated from the crural vessels and nerves. In the male subject, when the tendinous fibres, mixed with the cellular substance covering the outer opening of the passage, make great resistance at particular points, the hernial sac of a femoral hernia may be double, or even divided into several pouches, a preparation exhibiting which occurrence, is in the anatomical museum at Würzburg.—(*Hesselbach*, *p.* 48.) Except in a few cases in which the origin and course of the epigastric artery are unusual, this vessel runs very close to the external side of the neck of the hernial sac, much nearer than it does in an internal bubonocele.

The sac of the femoral hernia is exceedingly narrow at its neck; and where its body begins, it becomes expanded in a globular form; the sac of the bubonocele is generally of an oblong pyramidal shape. The body of the sac of the femoral hernia makes a right angle with the neck by being thrown forwards and upwards, a circumstance very necessary to be known in trying to reduce the parts by the taxis. Though the tumour formed by the body of the sac, is oval and nearly transverse, it is found, when attentively examined, to take the direction of the groin, which extends obliquely downwards and inwards, the outer rather smaller end of the swelling being somewhat higher than the inner.—(*Hesselbach*, *p.* 50.)

The sac of the femoral hernia is said by Sir A. Cooper to be covered by a kind of membranous expansion, consisting of condensed cellular substance, and named by him the *fascia propria*, which is thus described: "A thin fascia naturally covers the opening through which the hernia passes, and desends on the posterior part of the pubes. When the hernia, therefore, enters the sheath, it pushes this fascia before it, so that the sac may be perfectly drawn from its inner side, and the fascia which covers it left distinct. The fascia which forms the crural sheath, and in which are placed the hole or holes for the absorbent vessels, is also protruded forwards, and is united with the other, so that the two become thus consolidated into one. If a large hernia is examined, the fascia is only found to proceed upwards, as far as the edge of the orifice on the inner side of the crural sheath by which the hernia descends; but in a small hernia it passes into the abdomen, as far as the peritoneum, and forms a pouch, from which the hernial sac may be withdrawn, leaving this, forming a complete bag over the hernia."—(*On Hernia*, *part* 2, *p.* 6.) However, Mr. Lawrence has not been able to find, on dissection, the above mentioned thin fascia, said to cover the opening through which the hernia passes; nor does his account refer any covering of the hernia, in ordinary cases, to an elongated production of the sheath for the crural vessels. According to Sir Astley Cooper, a weak aponeurosis, derived from the superficial fascia of the bend of the

thigh, covers the swelling, and lies immediately beneath the skin and adipose substance. Under this fascia is the condensed cellular substance or fascia propria joined with the expansion of the crural sheath, then some adipose substance, and lastly, the true peritoneal sac itself. It is of infinite use to remember these several investments in operating, lest one should think the hernial sac divided when it is not so.

All late writers on hernia have remarked how very small the aperture is, through which the viscera protrude in the femoral rupture; how much greater the constriction generally is than in the bubonocele; consequently, how much more rapid the symptoms are; how much less frequently the taxis succeeds; and how much more dangerous delay proves.—(See *Sir A. Cooper*, *Hey*, *Lawrence*, *&c.*)

Though the crural ring is almost always small, yet, in a few instances, in which the tumour is large, and of long standing, it becomes very capacious, just as the opening often becomes, through which the inguinal hernia protrudes. Dr. Thomson of Edinburgh, Mr. Hey, and Mr. Lawrence have related examples of this kind.

The remarks already made concerning the treatment of hernia, before having recourse to the knife, are all applicable to the present case, and need not be repeated. In attempting to reduce the femoral hernia by the taxis, the surgeon should recollect, however, that relaxing Poupart's ligament, and the femoral fascia, is of the highest consequence. Hence the thigh should be bent, and rolled inwards. The pressure ought also to be first made downwards and backwards, in order to push the swelling off Poupart's ligament; and afterward, the parts should be propelled upwards, so that they may return through the crural ring.

OPERATION FOR THE FEMORAL OR CRURAL HERNIA.

Sir A. Cooper says, "the incision of the integuments is to be begun an inch and a half above the crural arch, in a line with the middle of the tumour, and extended downwards to the centre of the tumour below the arch. A second incision, nearly at right angles with the other, is next made, beginning from the middle of the inner side of the tumour, and extending it across to the outer side, so that the form of this double incision will be that of the letter T reversed." The angular flaps are, of course, to be next dissected off and reflected. Dupuytren also makes the external wound of a similar shape, the first cut being always parallel to the femoral vessels.—(*Breschet. op. cit. p.* 169.)

The making of two incisions, however, is not deemed necessary by the majority of surgeons; and in all the numerous operations which I have seen performed in St. Bartholomew's Hospital, during my apprenticeship there, and afterward, a transverse wound was not necessary. The division of the skin should begin about an inch above the crural ring, and be continued obliquely downwards and outwards. In this manner we cut exactly over the place where the incision of the stricture should be made.—(See *Lawrence*, *p.* 425, *ed.* 4.)

"The first incision (Sir A. Cooper remarks) exposes the superficial fascia, which is given off by the external oblique muscle, and which covers the anterior part of the hernial sac; but if the patient is thin, and the hernia has not been long formed, this fascia escapes observation, as it is then slight and delicate, and adheres closely to the inner side of the skin. When this fascia is divided, the tumour is so far exposed, that the circumscribed form of the hernia may be distinctly seen: and a person not well acquainted with the anatomy of the parts, would readily suppose that the sac itself was now laid bare. This, however, is not the case; for it is still enveloped by a membrane, which is the fascia that the hernial sac pushes before it, as it passes through the inner side of the crural sheath. This membrane, the fascia propria, is to be next divided longitudinally from the neck to the fundus of the sac; and if the subject is fat, an adipose membrane lies between it and the sac, from which it may be distinguished, by seeing the cellular membrane passing from its inner side to the surface of the sac.

"This is, in my opinion, the most difficult part of the operation; for the fascia propria is very liable to be mistaken for the sac itself; so that when it is divided, it is supposed that the sac is exposed, and the intestine is laid bare; following upon this idea, the stricture is divided in the outer part of the sac, and the intestine, still strangulated, is pushed, with the unopened sac, into the cavity of the abdomen.

"The hernial sac being exposed, is to be next opened; and to divide it with safety, it is best to pinch up a small part of it between the finger and thumb; to move the thumb upon the finger, by which the intestine is distinctly felt, and may be separated from the inner side of the sac; and then to cut into the sac, by placing the blade of the knife horizontally. Into this opening a director should be passed, and the sac opened from its fundus to the crural sheath."—(*On Crural and Umbilical Hernia.*)

Sometimes the contents of the hernia, thus exposed, admit of being returned without the further use of the knife. When this object, however, cannot be readily done, the protruded parts should never suffer injury from repeated manual attempts; and it is best to divide the stricture at once.

The merit of having first proposed the safest plan of cutting Poupart's ligament, even before surgeons were aware of the parts which really form the strangulation, is assigned by Gimbernat to Mr. B. Bell, who introduced his finger below Poupart's ligament, between the ligament and the intestine (an evident proof, says Gimbernat, that there was no strangulation there); he then made a very superficial incision from above downwards into the thickest part of the ligament to its lower edge; and without cutting quite through it, he continued his incision about an inch. He rested the back of the scalpel upon his finger, which served as a guide to the instrument, and, at the same time, as a defence to the intestine. The incision, however, having been continued for an inch, would, as Gimbernat remarks, inevitably cut the internal edge of the crural arch. Now cutting this only for a few lines gives sufficient room for the easy reduction of the parts; and there is no necessity to touch the ligament, as it never occasions the strangulation.—(*Gimbernat*, *p.* 27.)

Gimbernat's method of dividing the stricture, in cases of femoral herniæ, is now frequently regarded as the safest and most effectual. "Introduce, along the internal side of the intestine, a cannulated or grooved sound, with a blunt end, and a channel of sufficient depth. This is to be directed obliquely inwards, till it enter the crural ring, which will be known by the increased resistance; as also when its point rests upon the branch of the os pubis. Then suspend the introduction; and keeping the sound (with your left hand, if you are operating on the right side, and v. v.) firmly resting upon the branch of the os pubis, so that its back shall be turned towards the intestine, and its canal to the symphysis pubis, introduce gently with your other hand, into the groove of the sound, a bistoury with a narrow blade and blunt end, till it enter the ring. Its entry will be known, as before, by a little increase of resistance. Cautiously press the bistoury to the end of the canal; and employing your two hands at once, carry both instruments close along the branch to the body of the pubis, drawing them out at the same time. By this easy operation, you will divide the internal edge of the crural arch at its extremity, and within four or five lines of its duplicature; the remainder continuing firmly attached by the inferior band, or pillar, of which it is the continuation. This simple incision being thus made, without the smallest danger, the internal border of the arch, which forms the strangulation, will be considerably relaxed, and the parts will be reduced with the greatest ease.—(*Gimbernat*, *p* 45, 46.)

Mr. Lawrence thus executes Gimbernat's plan: "It will generally be practicable (says he) to introduce the tip of the finger, or of the nail under the edge of the tendon, the fibres of which should be carefully divided in succession, with the probe-pointed knife, until we have gained just sufficient room to replace the contents of the swelling. When the tightness of the stricture prevents the operator from using his finger as a guide, he will employ the deeply-grooved curved director, introducing it as near as he can to the pubes. In both cases, the blunt end only of the curved knife should be passed beyond the stricture, that the division may be effected without risk to the arteries, in case they should not follow their usual course." The intestine should be protected by the operator's left forefinger, or, if that cannot be spared, it may be held aside by an assistant.—(*On Ruptures*, *p.* 432, *ed.* 4.)

Sir A. Cooper recommends the stricture to be divided "obliquely inwards and upwards, at right angles to the crural arch." In consequence of the very deep situation of the posterior edge of the crural arch, and the tight manner in which the protruded viscera are surrounded by the tendon, this excellent surgeon considers, that the intestine is in great danger of being wounded with the knife, or, if held aside sufficiently, of being torn. Hence, his custom is to divide the stricture on its anterior part, as far as the front margin of the crural arch, directing the edge of the knife upwards and inwards. If this is not sufficient, he afterward cuts the thin posterior border of the tendon in the same direction.

After advising us to open the sac of a femoral hernia with particular care, on account of its being much thinner than that of a bubonocele, and (as might be added) on account of its seldom containing any fluid, and often having no omentum in it covering the intestine, Mr. Hey remarks: "The stricture made upon the prolapsed parts is very great, as I have already observed; but if the tip of the finger can be introduced within the femoral ring to guide the bubonocele knife, a small incision (for the ring is narrow) will be sufficient to set the parts at liberty. If the tip of the finger cannot be introduced at the proper place, a director with a deep groove must be used instead of the finger; but I prefer the latter. The finger or director should not be introduced very near the great vessels, but on that side of the intestine or omentum which is nearest to the symphysis of the ossa pubis. *The incision may then be made directly upwards.* The surgeon must take especial care to introduce his finger or director within that part where he finds the stricture to be the greatest, which, in this species of hernia, is the most interior part of the wound."—(*P.* 155.)

Gimbernat's mode is preferable to Mr. Hey's, because, were the operation done on a male, cutting directly upwards would endanger the spermatic cord. In order to obviate this risk, Sir A. Cooper makes a small incision above Poupart's ligament, and draws the cord out of the way of the knife, with a bent probe.

Mr. Lawrence has noticed that an "incision of the most interior part of the stricture is free from all danger, in the ordinary course of the vessels. But that variety, in which the obturatrix artery, arising from the epigastric, runs along the inner margin of the sac, seems to preclude us from cutting even in this direction." Hesselbach met with a remarkable instance of such irregularity in the origin and course of the obturatrix artery in the body of a female, in whom there were two small crural herniæ. On the right side, the epigastric and obturatrix arteries arose, by a common trunk, from the crural artery below Poupart's ligament. They soon separated from one another; the epigastric taking its ordinary course upwards at the outer side of the neck of the hernial sac, while the obturatrix made a considerable turn, and ran transversely inwards over the strong fibres of the femoral ligament, and encircled the anterior and inner side of the neck of the hernia, whence it afterward proceeded obliquely downwards and outwards, behind the horizontal branch of the os pubis, towards the obturator foramen.—(*Hesselbach, p.* 52.) A mode of operating has lately been proposed (*Edin. Med. and Surg. Journal, vol.* 2, *p.* 205), with a view of avoiding this danger. We are directed to make an incision through the aponeurosis of the external oblique muscle, just above the crural arch, and in a direction parallel to that part; to introduce a director under the stricture from this opening, and to divide the tendon to the requisite extent, by means of a curved knife passed along the groove.—(*On Ruptures, p.* 430, *edit.* 4.) For reasons which Mr. Lawrence states, this plan is certainly not altogether eligible, and, upon the whole, Gimbernat's method of cutting the stricture is the safest. Dupuytren uses a curved probe-pointed bistoury, that cuts with its convexity: it is conducted flat on the left forefinger, and with it under the stricture, and then its edge is turned upwards, the incision being extended through the upper end of the falciform process to the margin of the crural arch.—(*Breschet Concours, &c. p.* 182.)

Monro computes, that the obturator artery may arise from the epigastric, once in twenty five or thirty subjects. But allowing that it originates more frequently, it then does not always deviate from its usual course along the outside of the sac. Sir A. Cooper says; "In all cases which I have myself dissected, where this variety existed with crural hernia, the obturator has passed into the pelvis, on the outer side of the neck of the sac, entirely out of the reach of any danger of the knife."—(*On Crural Hernia, p.* 21.) Mr. Lawrence concludes, that the comparative number of instances, in which it is found on the opposite side, cannot be more than one in twenty, and consequently, if we admit that the obturatrix artery arises from the epigastric once in five times, it would only be liable to be wounded once in a hundred operations.—(*P.* 412, *ed.* 3.)

When the origin and course of the epigastric artery differ from what is common, this vessel, as Hesselbach remarks, sometimes passes inwards along the horizontal branch of the os pubis, ere it ascends towards the rectus muscle, and when this variation exists in a case of femoral hernia, the artery does not pass over the outer side of the neck of the sac, but first under it, and then round its inner side. Hesselbach has seen only one instance of this irregularity of the epigastric artery in a female, and never in a male subject.—(*Ueber den Ursprung, &c. der Leisten-und-Schenckelbrüche, p.* 52.)

The industrious Cloquet examined 250 bodies for the purpose of estimating the average number of cases, in which the origin and course of the obturatrix artery are different from what is most common. He found, that when this artery and the epigastric arise by one common trunk, they sometimes separate from each other above, and rarely below the upper opening of the crural canal. In the first case, the longer their common trunk is, the closer do they lie to Gimbernat's ligament, and to the inner edge of the upper opening of the above canal. In the second case, the common trunk of these arteries arises within this canal, and the two vessels then return into the abdomen. In 160 bodies, of which 87 were male, and 73 female, the obturatrix artery arose on both sides from the hypogastric; and only in 56, of which 21 were male, and 35 female, did it originate on both sides from the epigastric. In 28, of which 15 were male, and 13 female, the obturatrix arose on one side from the hypogastric, and on the other from the epigastric. In six bodies, viz. two male and four female, it originated from the crural.—(*Rech. Anat. sur les Hernies*, 4*to. Paris.*)

It is observed by Professor Scarpa that "the round ligament of the uterus, in passing through the abdominal muscles, follows precisely the same track as the spermatic cord. It is equally situated behind Poupart's ligament, with the difference, that it does not become so distinct from the internal extremity of this ligament, as the spermatic cord does, because it has not so far to run, in order to get from that ligament to the inguinal ring, the latter opening being situated lower in the female than the male subject. The round ligament, like the spermatic cord, also crosses the epigastric artery before reaching the inguinal ring. And as the crural hernia always begins at the internal and inferior angle of the arch of this name, as well in the male as the female, it follows that, in the two sexes, the epigastric artery remains in its natural situation, and invariably corresponds to the external side of the neck of the crural hernia; while the spermatic cord in men, and the round ligament in women, pass over the extremity of the front of the neck of the hernial sac. In the operation for the crural hernia, in females, the incision of the neck of the hernial sac and crural arch, when directed upwards towards the linea alba, cannot wound the epigastric artery, which it is of the most consequence to avoid; but it always divides, either totally, or partially, the round ligament of the uterus, which cannot lead to any dangerous hemorrhage; for, except in the period of pregnancy, the arteries of the round ligament are very small; they are almost obliterated in women advanced in years; and, in general, they are quite capillary in the extremity of the ligament adjoining the ring. Hence, it cannot be surprising that so many crural herniæ have been successfully operated upon in women by cutting the hernial sac and crural arch directly upward, while not a single instance can be cited of such an incision being made in man without mischief, although, in both sexes, the epigastric artery may have been avoided in operating by this process.—(*Scarpa, Traité des Hernies, p.* 240.)

In operating upon the crural hernia in males, Scarpa recommends us to follow a method, which he calls new, but which, in fact, is the same as that advised by Gim

hernat. "I have found (says Scarpa) that, in man, the neck of the hernial sac may be divided without danger, by giving to the incision a direction exactly contrary to that which is practised in the female subject. After having opened the hernial sac, it is to be drawn outwards by one of its sides sufficiently to allow the introduction of a small director between its neck and the strangulated intestine, *the groove of the instrument being turned downwards towards the internal and inferior angle of the crural arch. A probe-pointed bistoury, the edge of which is also to be directed downwards towards the point of insertion of Poupart's ligament to the pubes, is to be pushed along the groove. By this means the neck of the hernial sac will be divided its whole length at its internal and inferior side, and Poupart's ligament will be cut close to its attachment to the top of the os pubis.* The epigastric artery will certainly be avoided, because it lies upon the opposite side of the hernial sac. As for the spermatic cord, I have demonstrated, that it is situated on the fore part of the neck of the hernial sac; consequently it cannot be touched by an incision made from above downwards, while it is constantly cut in the ordinary method, since the knife is carried from below upwards. In the first case this part may be the more easily avoided, as it lies at some distance from the internal and inferior angle of the crural arch. In fact, it is at this place that it quits, as we have seen, the edge of Poupart's ligament, in order to ascend towards the inguinal ring. The incision that I propose (says Scarpa) not only has the advantage of slitting open the neck of the hernial sac its whole length, it also divides a part of the insertion of Poupart's ligament into the upper part of the os pubis, a thing that greatly contributes to relax the crural arch, and facilitate the reduction of the viscera; of those, at least, which are not adherent to the sac."—(*Scarpa, op. cit. p.* 235.)

Although this accurate anatomist and surgeon, at the time when he first published on hernia, was quite unacquainted with the valuable works on the same subject, which had made their appearance in this country, it is curious to find, both in his account of the inguinal and crural hernia, how strongly his doctrines and observations tend to confirm every thing that has recently been insisted upon in modern works, respecting the place where the bubonocele first protrudes, its passing through a sort of canal before it comes out of the abdominal ring, the advantage of cutting in the crural hernia the internal and inferior angle of Poupart's ligament, or, in other terms, that part of the ligament which was first particularly pointed out by Gimbernat, as causing the principal part of the strangulation.

Hesselbach considers an incision through the outer side of the crural ring safer than one through Gimbernat's ligament, and safer in women than men. In women, he recommends the cut to be made through the middle of the fore part of the ring, nearly straight upwards, or a little inclined inwards, in which mode the epigastric artery cannot be hurt, whether it lie at the outer or inner side of the neck of the sac. In men, this incision, directed obliquely upwards and inwards, he says, cannot be made, on account of the nearness of the spermatic cord; therefore, in the male subject, he advises cutting the inner side of the opening, that is to say, Gimbernat's or the femoral ligament, directly inwards towards the symphysis of the os pubis.—(*Ueber den Ursprung der Leisten-und-Schenkelbrücke, p.* 54.) When the epigastric or obturator artery deviates from its usual course, and surrounds the inner side of the neck of the hernia (which variety can never be ascertained *a priori*), a wound of the vessel Hesselnach regards as unavoidable.

From the views taken of femoral hernia in this article, I consider the unrestricted direction always to cut Gimbernat's ligament in the operation perfectly erroneous. For, as Langenbeck has stated, the seat of strangulation may either be in the external aperture of the crural canal, or in an opening of the front or inner side of this passage, or in its inner opening, where indeed Gimbernat's ligament is truly concerned. When the strangulation is of the first two descriptions, only the fascia lata need be cut; but in the third, most frequent case, the inner semilunar edge of the internal opening of the ring must of course be divided. In all cases, says Langenbeck, whether the strangulation be caused by the inner or external opening of the crural canal, or by an aperture in the front parietes of this passage, the stricture must be cut inwards, as directing the cut in the least outwards would injure the epigastric artery. When it is perceived, in the operation, that the neck of the hernial sac is strangulated close below and behind the external pillar of the abdominal ring, then the inner opening of the crural canal must be divided inwards, with the knife directed along the horizontal ramus of the os pubis, under the external pillar of the ring, towards the symphysis of the pubes. If, in such a case, the knife were carried inwards and upwards, that part of Poupart's ligament forming the upper side of the crural canal, might be cut, and the spermatic artery injured.—(*Neue Bibl. b.* 2, *p.* 133.)

Dr. Trüstedt has published some remarks, in favour of employing dilatation, instead of an incision, in the operation for the strangulated crural hernia. He observes, that even when the common trunk of the obturatrix and epigastric arteries is short, the bowels may protrude under the first of these arteries, which will lie upon the upper and inner side of the hernia. In an operation performed upon a woman, in La Charité at Berlin, for a strangulated femoral hernia, the crural ligament was divided in Gimbernat's way by an incision, exactly parallel to the horizontal ramus of the os pubis, and the obturatrix artery was wounded. The patient died eight days after the operation, having been previously attacked by trismus and opisthotonos. On dissection, about six ounces of putrid blood were found in the lesser cavity of the pelvis, and the above artery cut. The vessel arose from the epigastric, ran over the upper edge of the inner opening of the crural canal, or ring, and then descended along its inner edge, towards the obturator foramen. This occasional course of the obturatrix artery leads Dr. Trüstedt to suggest the following rules: if, after the hernial sac is opened, the bowels cannot be returned, the outer opening of the crural canal should be cut directly inwards, in order to produce a considerable relaxation. But, if the reduction should yet be impracticable (the strangulation being at the inner opening of the canal), then an attempt is to be made to insinuate the end of the finger through the constriction, a plan said to have answered very often in the practice of surgeon-general Rust. Should the resistance be too great, however, for this method to succeed, Trüstedt advises the crural ligament to be forcibly drawn inwards and upwards, towards the navel, with Arnaud's tenaculum, assisted by the introduction of the finger, or with two hooks. When this plan fails, he recommends Schreger's practice of dividing the anterior edge of Poupart's ligament with a pair of blunt-pointed scissors, and then the use of Arnaud's tenaculum again.—(See *Rust's Magazin für die gesammte Heilkunde, b.* 3, *h.* 2.) The consideration, however, which will ever prevent the common adoption of Dr. Trüstedt's suggestion, is, that fifty times more lives would be lost by the mischief done to the protruded bowels by the forcible introduction of the fingers and hooks, than by hemorrhage from the obturatrix or epigastric artery, when the course of the vessel is irregular.

Of late years, a fact of considerable interest has been ascertained in relation to femoral hernia; viz. that the constriction of the bowel by the smallness of the aperture and the sharp edge of Poupart's ligament, is so great, that either a permanent contraction of the part, ulceration of the internal and muscular coats, or even that of the serous coat also may occur, followed by fatal extravasation, after the reduction of the hernia by the operation.—(*Chevalier, in Med. Chir. Trans. vol.* 4, *p.* 324; *Breschet, op. cit. obs.* 2; *Lawrence, p.* 442, *ed.* 4.) Hence, the latter gentleman is an advocate for gently drawing out the bowel, after liberating it from stricture: if no reason be found to apprehend perforation of the tube, he advises its reduction; but, in the opposite case, he directs it to be left out of the abdomen, rather than that the patient should be exposed to the danger of effusion into the abdomen.—(*P.* 444.)

CONGENITAL HERNIA.

Before the beginning of the sixth month of the fœtal state, the testicle is situated near the kidney, where it receives a covering from the peritoneum, just like the other abdominal viscera. Between the beginning of the sixth month, and end of the seventh, the testicle has either descended as low as just above the abdo-

minal ring, or else is passing through it, or arrived a little below it.—(*Wrisberg, Com. Reg. Societ. Gotting.* 1785.)

When the testicle passes through the abdominal ring into the scrotum, it is received into a production of the peritoneum, which afterward constitutes the tunica vaginalis; while that peritoneal investment, which was given to the testicle in the loins, is closely adherent to this body, and forms what is named the tunica albuginea.

After the descent of the testicle into the scrotum, the communication between the cavity of the tunica vaginalis and that of the abdomen commonly becomes obliterated, which latter event is usually effected before birth, sometimes not till afterward, and, in a few subjects, even as late as the adult state.

In the congenital hernia the protruded viscera are situated in the tunica vaginalis, in contact with the testicle; having descended into this position before the closure of the communication with the abdomen. Of course, the tunica vaginalis itself is the hernial sac. The nature of this case was not understood, before it was elucidated by Haller in 1755, and the two Hunters in 1762 and 1764.—(See *Hunter's Med. Comment.*; *Haller's Opuscula Patholog. and Opera Minora*, *t.* 3.) Many particulars, relative to the origin and formation of this hernia, having been given in the fifth edition of the *First Lines of Surgery*, I shall not here repeat them. Before the periods now named, surgeons imputed the circumstance of the contents of the hernia and testicle being in contact, to the bowels having made their way, by laceration, through the tunica vaginalis, from the ordinary hernial sac of a bubonocele. The old surgeons, indeed, frequently cite this instance, in proof of their doctrine, that some herniæ are attended with a laceration of the peritoneum.—(See *Sharp's Inquiry.*)

From the term *congenital*, we might suppose, that this hernia always existed at the time of birth. The protrusion, however, seldom occurs till after this period, on the operation of the usual exciting causes of herniæ in general. It does not commonly happen till some months after birth; and, in certain instances, not till a late period. Mr. Hey relates a case, in which a hernia congenita was first formed in a young man, aged sixteen, whose right testis had, a little while before the attack of the disease, descended into the scrotum. In the generality of cases which actually take place when the testicle descends into the scrotum before birth, the event may be referred to the testicle having contracted an adhesion to a piece of intestine, or omentum, in its passage to the ring. In an infant, which died a few hours after birth, Wrisberg found one testicle, which had not passed the ring, adhering, by means of a few slender filaments, to the omentum, just above this aperture. Sometimes, adhesions of the testicle to the adjacent viscera, instead of leading to the formation of a congenital hernia, only prevent the descent of the former organ. Cloquet examined the body of an old man, in which the left testicle lay on the psoas and iliacus muscles, connected to the sigmoid flexure of the colon, while an inguinal hernia existed on the same side.—(*Recherches, &c. p.* 24.) Sometimes, no protrusion at all happens, even though the communication between the tunica vaginalis and abdomen continue open in the adult subject, as is particularly exemplified in a case recorded by Hesselbach, where such communication existed on each side in a man thirty-eight years of age, without any hernia.—(*Med. Chir. Zeitung*, 1819, *p.* 110. Also, *A. Cooper*, in *Lancet*, *vol.* 2, *p.* 173.)

The appearance of a hernia in very early infancy, Mr. Pott observes, will always make it probable that it is of this kind; but he was not correct in asserting, that in an adult there is no reason for supposing his rupture to be of this sort, but his having been afflicted with it from his infancy: and that there is no external mark or character whereby it can be certainly distinguished from one contained in a common hernial sac. This statement is erroneous, inasmuch as the hernia congenita is attended with an impossibility of feeling the testis, which part in the common scrotal hernia is always distinguishable under the fundus of the hernial sac. The hernia congenita, when returnable, "ought, like all other kinds of ruptures, to be reduced, and constantly kept up by a proper bandage; and when attended with symptoms of stricture, it requires the same chirurgic assistance as the common hernia."

Mr. Pott notices, that "in very young children, a piece of intestine, or omentum, may get pretty low down in the sac, while the testicle is still in the groin, or even within the abdomen In this case, the application of a truss would be highly improper; for, in the latter, it might prevent the descent of the testicle from the belly into the scrotum; in the former, it must necessarily bruise and injure it, give a great deal of unnecessary pain, and can prove of no real use. Such bandage, therefore, ought never to be applied on a rupture in an infant, unless the testicle can be fairly felt in the scrotum, after the gut or caul is replaced; and, when it can be so felt, a truss can never be put on too soon." This is also the advice delivered by Sir A. Cooper.

As Mr. Pott has explained, an old rupture, originally congenital, is subject to a stricture made by the sac itself, as well as to that produced by the abdominal ring, or, as might have been added, to that caused by the inner opening of the inguinal canal.

The fact he noticed several times, both in the dead and in the living. "I have seen (says he) such stricture made by the sac of one of these herniæ, as produced all those bad symptoms which render the operation necessary: and I have met with two different strictures, at near an inch distance from each other, in the body of a dead boy, about fourteen, one of which begirt the intestine so tight that I could not disengage it without dividing the sac.

"In this kind of hernia I have also more frequently found connexions and adhesions of the parts to each other than in the common one; but there is one kind of connexion sometimes met with in the congenital hernia, which can never be found in that which is in a common hernial sac, and which may require all the dexterity of an operator to set free; I mean that of the intestine with the testicle.

"If a large quantity of fluid should be collected in the sac of a congenital hernia, and, by adhesions and connexions of the parts within, the entrance into it from the abdomen should be totally closed, (a case which I have twice seen,) the tightness of the tumour, the difficulty of distinguishing the testicle, and the fluctuation of the fluid, may occasion it to be mistaken for a common hydrocele; and if without attending to other circumstances, but trusting merely to the feel and look of the scrotum, a puncture be hastily made, it may create a great deal of trouble, and possibly do fatal mischief."—(*Works*, *vol.* 2.)

Mr. Pott also believed, that common ruptures, or those in a peritoneal sac, are generally gradually formed, that is, they are first inguinal, and by degrees become scrotal; but that the congenital are seldom remembered by the patient to have been in the groin only. As the tunica vaginalis is thicker than the peritoneum, the contents of a congenital hernia are not so easily felt as those of a common rupture. In children the hernia generally contains intestine only, the omentum not being in them sufficiently long commonly to protrude.

The sac of a congenital hernia, especially when the case is strangulated, is every where equally tense, (*Hesselbach*, *p.* 36,) and below it the testis cannot be felt.

The reader must not conclude, however, from the above account, that every rupture in children is congenital. Mr. Lawrence has related a case of strangulated bubonocele, which took place in an infant only fourteen months old.—(*P.* 65, *edit.* 3.)

The common inguinal hernia, which first protrudes at the inner opening of the inguinal canal, and which has the epigastric artery on the inner side of its neck, has been named by Hesselbach *external;* while the less common instance, in which the viscera burst directly through the aponeuroses of the transverse and internal oblique muscles, and pass directly out of the abdominal ring, leaving the epigastric artery on the outer side of the neck of the sac, is distinguished by the epithet *internal.*—(*Anat. Chir. Abhandlung über den Ursprung der Leistenbrüche; Würzb.* 1806.) "The inguinal congenital hernia (says Scarpa) cannot be divided into *external* and *internal;* it is evident that it must always be external, since the neck of the tunica vaginalis invariably corresponds to the point, at which the spermatic cord passes under the margin of the transverse muscle. As for other circumstances, the tunica vaginalis lies in its whole course in the same

manner as the sac of a common inguinal hernia: like this, it passes completely through the inguinal canal from one end to the other, resting upon the anterior surface of the spermatic cord. Consequently it passes between the separation of the inferior fibres of the obliquus internus, and the principal origin of the cremaster muscle.—(See *Wrisberg, Syllog. Comment. Anat. p.* 23.) After coming out of the ring, as it is always united to the spermatic cord, it is enclosed in the muscular and aponeurotic sheath of the cremaster muscle, which accompanies it to the bottom of the scrotum. Since the tunica vaginalis, including the displaced viscera, enters the inguinal canal on the outside of the point at which the spermatic cord crosses the epigastric artery, it is manifest, that, as it follows exactly the direction of this cord, it must also cross the artery, and remove it from the outer to the inner side of the ring, according to the mechanism already explained in speaking of the common inguinal hernia. Hence, the displacement of the epigastric artery constantly happens in the inguinal congenital, just as it does in the ordinary external inguinal hernia.

"But if these two species of inguinal herniæ have some analogy to each other, in regard to the parts which constitute them, yet they present some remarkable differences. 1. The common inguinal hernia, whether internal or external, when it extends into the scrotum, cannot descend beyond the point at which the spermatic vessels enter the testicle. There the cellular substance of the spermatic cord terminates. There the hernial sac must also unavoidably terminate. On the contrary, in the congenital hernia, the viscera may descend lower than the testicle, with which they are in immediate contact; and, at length, they even occupy the situation of this organ, which is then pushed upwards and backwards. 2. In the case of a congenital hernia, the descent of the viscera from the groin to the scrotum commonly takes place in a very short time, and in some measure precipitately: it is much slower and more gradual in the ordinary inguinal hernia. The reason of this difference is very plain. In the first case, the descent of the testicle, and the formation of the tunica vaginalis, have opened and prepared the way, which the viscera must follow in forming a protrusion; while, in the second, the hernial sac cannot descend into the scrotum, but by gradually elongating the layers of the cellular substance which joins it to the surrounding parts. This fact is so generally known, that experienced practitioners consider the promptitude with which the viscera have descended from the groin to the bottom of the scrotum, as a characteristic sign of a scrotal congenital hernia."—(*Scarpa, Traité des Hernies, p.* 73, *&c.*; *Hesselbach, p.* 35; *Pott, &c.*)

In the hernia congenita the spermatic artery and vein are sometimes on one side of it, and the vas deferens behind it. A preparation, exhibiting this alteration of the cord, may be seen in the museum of St. Thomas's Hospital.

If circumstances will admit of a truss being applied and worn in cases of congenital hernia, in young subjects, there will be a considerable chance of a radical cure being effected, in consequence of the natural propensity of the opening between the abdomen and tunica vaginalis to become closed.

In the operation the surgeon has to lay open the tunica vaginalis, instead of a common hernial sac; but, as Sir Astley Cooper judiciously recommends, that membrane should not be opened low down; 1st, because a sufficiency of it should always be left to cover the testicle; and, 2dly, because the spermatic artery and vein are situated obliquely on the front and lower portion of the tumour. He therefore directs three inches of the lower part of the tunica vaginalis to be left undivided.—(See *Lancet, vol.* 2, *p.* 175.) The stricture is to be divided on the same principle as that of an inguinal hernia, and much in the same manner. As, in a case of congenital hernia, the parts are always protruded on the outside of the epigastric artery, the stricture may be safely divided towards the ilium, as well as directly upwards.—(*Lawrence on Ruptures, p.* 307, *ed.* 4.) According to Sir Astley Cooper, the stricture is generally about an inch and a half from the abdominal ring, except in large cases, when it is nearer to it. The parts having been reduced, the edges of the wound are to be immediately brought together, and retained so by means of one or two sutures and sticking plaster, which is much preferable to the old plan of applying dressings to the testicle and inside of the tunica vaginalis, so as to heal the part by the granulating process.

A new species of hernia congenita was described by the late Mr. Hey, in which a common peritoneal hernial sac, containing the viscera, is included in the tunica vaginalis. It arises from the parts being protruded, after the communication between the abdomen and tunica vaginalis is closed, so that the peritoneum is carried down along with the intestine, and forms a hernial sac within the tunica vaginalis. It is evident, also, that such a hernia can only be produced while the original tunica vaginalis remains, in the form of a bag, as high as the abdominal ring. Operators should be aware of the possibility of having a sac to divide after laying open the tunica vaginalis.—(See *Hey's Practical Obs. p.* 221, *Dr. Ballingall, in Edin. Med. Journ. No.* 87, *p.* 464; and *Sir A. Cooper's Work on Inguinal Hernia, p.* 59.)

UMBILICAL HERNIA, OR EXOMPHALOS.

"The exomphalos, or umbilical rupture, (says Pott,) is so called from its situation, and has (like other herniæ) for its general contents, a portion of intestine, or omentum, or both. In old umbilical ruptures the quantity of omentum is sometimes very great. Mr. Ranby says, that he found two ells and a half of intestine in one of these, with about a third part of the stomach, all adhering together. Mr. Gay and Mr. Nourse found the liver in the sac of an umbilical hernia; and Bohnius says that he did also. But whatever are the contents, they are originally contained in the sac, formed by the protrusion of the peritoneum. In recent and small ruptures this sac is very visible; but in old and large ones, it is broken through at the knot of the navel, by the pressure and weight of the contents, and is not always to be distinguished; which is the reason why it has by some been doubted whether this kind of rupture has a hernial sac or not.

"Infants are very subject to this disease in a small degree, from the separation of the funiculus; but in general they either get rid of it as they gather strength, or are easily cured by wearing a proper bandage. It is of still more consequence to get this disorder cured in females, even than in males, that its return, when they are become adult and pregnant, may be prevented as much as possible; for at this time it often happens, from the too great distention of the belly, or from unguarded motion when the parts are upon the stretch. During gestation it is often very troublesome, but after delivery, if the contents have contracted no adhesion, they will often return, and may be kept in their place by a proper bandage.

"If such bandage was always put on in time, and worn constantly, the disease might in general be kept within moderate bounds, and some of the very terrible consequences which often attend it might be prevented. The woman who has the smallest degree of it, and who, from her age and situation, has reason to expect children after its appearance, should be particularly careful to keep it restrained.

"In some the entrance of the sac is large, and the parts easily reducible; in others they are difficult, and in some absolutely irreducible. Of the last kind many have been suspended for years in a proper bag, and have given little or no trouble. They who are afflicted with this disorder, who are advanced in life, and in whom it is large, are generally subject to colics, diarrhœas, and, if the intestinal canal be at all obstructed, to very troublesome vomitings. (Hence, patients are often supposed to labour under a stricture when they really do not.) It therefore behooves such to take great care to keep that tube as clean and free as possible, and neither to eat or drink any thing likely to make any disturbance in that part."—(*Pott on Ruptures, vol.* 2.)

Authors who have published since the time of this celebrated surgeon, have not added much to the stock of information which he left, concerning the exomphalos. The writings of Sir A. Cooper, Scarpa, (*Traité des Hernies, p.* 327,) and all the most accurate moderns confirm the fact described by Pott, that in the umbilical rupture there is a hernial sac, just as in other instances of herniæ. Every one acquainted with anatomy knows, that behind the opening in the linea alba at the umbilicus, the peritoneum is complete, and consequently

must protrude along with the viscera in cases of exomphalos. In the only two cases which Sir A. Cooper has seen of a deficiency of the sac, the membrane had been partially absorbed, or lacerated, so as to allow the protrusion of its contents, and threaten, from this cause, a double stricture. Similar appearances, less closely inspected, probably gave rise to the opinion so firmly maintained by Dionis, De la Faye, Garengeot, and J. L. Petit, that, in the umbilical hernia, the peritoneum was always lacerated, and there was no hernial sac. According to Bichat, early infancy is most subject to the *umbilical* hernia, strictly so called, in which the parts protrude through the navel; while the other periods of life are more liable to false umbilical herniæ, or such as arise in the vicinity of the umbilicus.—(*Œuvres Chir. de Desault, t.* 2, *p.* 315.)

Besides a true hernial sac, the exomphalos is also covered by a more superficial expansion, consisting of condensed cellular substance. In operating, however, a surgeon should always cut with great caution; for the integuments and hernial sac in front of the tumour are inseparably adherent; and sometimes, in large cases, when an absorption of part of the sac has been caused by the pressure of the bowels, they are even found adherent to the integuments.

Pregnant women, and dropsical and corpulent subjects, are peculiarly liable to the exomphalos. In adults, when there is intestine in the sac, there is almost always omentum. The transverse arch of the colon is observed to be particularly often contained in umbilical hernia, but the small intestines are not unfrequently protruded: and even the cœcum has been found in a rupture at the navel.—(See *Lawrence on Ruptures*, *p.* 454, 455, *ed.* 4.)

In the true umbilical hernia, the stricture is made by the tendinous opening in the linea alba. Let us next consider the umbilical hernia in the three particular forms in which it has been noticed by the latest writers.

CONGENITAL UMBILICAL HERNIA.

Dr. Hamilton has met with about two cases of this kind annually for the space of seventeen years; and they strictly deserve the epithet *congenital*, as they appear at birth. The funis ends in a sort of bag, containing some of the viscera, which pass out of the abdomen through an aperture in the situation of the navel. The swelling is not covered with skin, so that the contents of the hernia can be seen through the thin distended covering of the cord. The disease is owing to a preternatural deficiency in the abdominal muscles, and the hope of cure must be regulated by the size of the malformation, and quantity of viscera protruded.

The plans of cure proposed consist of the employment of a ligature, or of a bandage. The latter seems preferable, and was practised by Mr. Hey, as follows: having reduced the intestine, he desired an assistant to hold the funis compressed sufficiently near the abdomen to keep the bowel from returning into the hernial sac.

"I procured (says he) some plaster spread upon leather, cut into circular pieces, and laid upon one another in a conical form. This compress I placed upon the navel, after I had brought the skin on each side of the aperture into contact, and had laid one of the lips a little over the other. I then put round the child's abdomen a linen belt; and placed upon the navel a thick, circular, quilted pad, formed about two inches from one extremity of the belt.

"This bandage kept the intestine securely within the abdomen, and was renewed occasionally. The funis was separated about a week after birth; and at the expiration of a fortnight from that time the aperture at the navel was so far contracted, that the crying of the child, when the bandage was removed, did not cause the least protrusion. I thought it proper, however, to continue the use of the bandage a little while longer. A small substance, like fungous flesh, projected, after the funis had dropped off, about half an inch from the bottom of that depression which the navel forms. A dossil of lint spread with cerat. e lapide calliminari, and assisted by the pressure of the bandage, brought on a complete cicatrization."—(*P.* 227.)

This gentleman has related another example, in which the intestines were quite uncovered and inflamed, the sac having burst in delivery. The parts were reduced; but the child died.—(See also *G. A Fried de Fœtu Intestinis plane nudis extra Abdomen propendentibus nato. Argent.* 1760.) [See p. 38.]

UMBILICAL HERNIA IN CHILDREN.

The umbilical hernia, which is sometimes formed in the fœtus, from causes difficult of explanation, takes place, in other instances, at the moment of delivery; and then, as Sabatier remarks, should it be tied by mistake with the funis, death would be the consequence. Most frequently, however, it is not till the second, third, or fourth month after birth that the disease occurs; and the numerous cases collected by Desault prove that, of ten infants attacked with this hernia nine become afflicted at the periods just mentioned.

The umbilicus, still open, now begins to contract, so as to close the cicatrix, which soon forms an obstacle capable of preventing a protrusion of the viscera. Sometimes, however, the repeated crying of the child propels the viscera through the opening, and thus the closure of the cicatrix of the navel is prevented. By degrees the umbilical ring becomes more and more dilated, the quantity of protruded bowel increases, and thus a tumour arises, which, from being of trivial size at first, at length attains the size of an egg, or large walnut, and presents itself with all the characteristic marks of a hernia.

The presence of a piece of intestine and omentum in the tumour, keeps the umbilicus open, and opposes the continual tendency which it has to close. Such tendency, however, being sometimes superior to the resistance of the protruded parts, forces them back into the abdomen, obliterates the opening through which they passed, and thus the spontaneous cure of the umbilical hernia in children is accomplished. Two cases illustrative of this fact are related by Bichat.—(*Œuvres Chir. de Desault, t.* 2, *p.* 318.)

Nature, however, does not effect many such cures, and when the case is left to her alone, she not only fails in bringing about a radical cure, but gradually renders it impossible. In short, the propensity of the opening to close diminishes, and is lost as the subject grows older.

Thus, the umbilical hernia of children seems to be essentially different from that of adults, in the tendency of the aperture to contract. Hence the ease of effecting a radical cure in children, and the almost utter impossibility of doing so in adults. In the former, it is enough to keep the intestines from protruding, and the opening becomes of itself obliterated; in the latter, the opening always remains, whether the bowels continue in it or not. This indisposition of the aperture to contract in the adult, also frequently depends upon the protrusion not being through the umbilical ring itself, but through a fissure in the vicinity of it, not endued with the same natural tendency to close, which the umbilicus possesses in young subjects. In fact, it would appear from the observations of Scarpa, that unless a grown up person has had the protrusion from infancy, it never occurs exactly through the umbilical ring itself.

The means of curing the umbilical hernia of children, are compression and the ligature. The former is the most modern; the latter the most ancient treatment, as it is mentioned by Celsus. The design of both is the same, viz. to prevent the lodgment of the protruded viscera in the opening of the umbilicus, and thus facilitate the approximation of its sides. To accomplish this end, the ligature retrenches the hernial sac and skin pushed before it; and by the union of the cut parts a cicatrix is produced, which hinders the protrusion of the viscera. At the same time, the sides of the opening obeying their natural tendency, compression closes the deficiency or opening, in the parietes of the abdomen, hinders the protrusion of the bowels, and keeps these parts from resisting the contraction of the sac. Desault remarks, that though compression occasions no pain, it is irksome, during the great length of time its employment is necessary. The ligature (he says) produces momentary pain; but it is not at all irksome, and it effects in a few days, what compression, when successful, accomplishes in several months. In one plan, long and continued attention is requisite, and if its employment be only for a short time neglected, the previous effect becomes almost destroyed. The other method always accomplishes its object with

certainty, independently of the crying of the child, and the care of its attendants. When compression is adopted, it is executed either by means of a flat compress applied to the opening, and which does not enter it, or else by means of some round or oval body, such as a ball of wax, a nutmeg, &c. adapted to the shape of the aperture, and, as Plattner and Richter (in his Treatise on Hernia) advise, continually kept within the opening. In the first case, Bichat argues, that if the bandage be exactly applied, the skin and sac will form a fold in the aperture of the navel, hinder its closure, and operate in the same manner, from without inwards, as the protruded intestines did from within outwards. In the second case, he observes, the foreign body being depressed into, and maintained in the opening, will occasion, notwithstanding what Richter says, the same inconveniences, and, in a more striking manner, similar consequences. But, on the contrary, when the ligature is employed, the sac and skin of the tumour are removed, while the opening remains free, and nothing prevents its obliteration. In this method, the omentum can never protrude outwards; but in the other, if the compression should ever be inexact, the parts slip out again, above or below, and the disorder prevails on one side of the useless application. The ligature is also commended as producing an adhesion of the sides of the opening, either to each other, or the adjacent parts. This adhesive process arises from the inflammation excited, and occasions a degree of firmness not producible by any other mode of cure. Desault's method, which much resembles that of Saviard, is described by Bichat.

The child must be placed on its back, with its thighs a little bent, and its head inclined towards the chest. The surgeon is to reduce the protruded parts, and to hold them so with his finger, at the same time that he raises the hernial sac, and rubs its sides between his fingers, so as to be sure that there is nothing contained in it. Being certain that the parts which he lifts up are only the skin and sac, he is to direct an assistant to surround their base several times with a waxed ligature of middling size, each turn being tied with a double knot, in such a manner as only to occasion little pain. The tumour thus tied, is to be covered with lint, which is to be supported with one or two compresses, and a circular bandage, secured with a scapulary. By the following day, a slight swelling has commonly taken place in the constricted parts.

On the second or third day the parts shrink, and then the ligature becomes loose, so that a fresh one must now be applied in the same manner as the first, taking care to draw it a little more tightly. The sensibility of the parts increased by the inflammation, which the constriction of the ligature has already produced, usually renders this second ligature more painful. After the operation, the same dressings as at first are to be applied. The tumour soon becomes discoloured, livid, and smaller. A third ligature put on in the same way as the preceding ones, entirely obstructs the circulation in it. The part turns black and flaccid, and commonly falls off on the eighth or tenth day. A small ulcer is left, which, being properly dressed, very soon heals, and leaves a cicatrix sufficiently strong to resist the impulse occasioned by coughing, or other efforts of the abdominal muscles. For two or three months, however, after the operation, the child should wear a circular bandage, in order to prevent, with still greater certainty, the viscera from being propelled against the cicatrix, so as to interrupt the process of nature, which is now producing a gradual closure of the umbilical opening. Numerous cases might here be adduced in confirmation of the above practice; but several (nine) are already published in the Parisian Chirurgical Journal.

One may doubt (says Sabatier), quoting the article in the Journal, where Desault treats of the present disease, whether the infants got rid of the hernia, as it might have returned some time afterward. To this observation Bichat replies, that numerous facts remove the doubt; for several of the subjects were brought to Desault's public consultation for other diseases, a long while after they had been operated upon, and the great number of students who examined them, all acknowledged that the ring was completely obliterated, and there was no impulse of the viscera in coughing, sneezing, &c. Other children, in the knowledge of the surgeons of the Hôtel-Dieu, remained perfectly cured, and Bichat was acquainted with two young subjects on whom the operation had been performed four years, and they had had no relapse.

In young infants the operation almost constantly answered; but in proportion as their age increased, it was found to be less certain. Bichat relates three cases which tend to prove, that success may be completely obtained at the age of a year and a half; that the cure is difficult when the child is four years old; and impossible when it is nine.—(See *Œuvres Chir. de Desault, t.* 2, *p.* 315, *&c.*)

Mr. Pott notices the plan of curing the exomphalos with the ligature, and expresses himself strongly against the practice in general. To adults the plan is not applicable, particularly when the tumour is large. Mr. Pott was decidedly in favour of compression, and he observes, that in young subjects and small herniæ, a bandage worn a proper time, generally proves a perfect cure.—(*Vol.* 2.)

Anxious that this work should be strictly impartial, I next proceed to relate what has been more recently urged against the employment of the ligature for the cure of the umbilical hernia in children.

The incessant care that a bandage requires, either to keep it clean, or to make it always keep up the proper degree of pressure, renders its employment difficult in the children of the poorer classes. Scarpa expresses his opinion, that this was what induced Desault to revive the operation for the umbilical hernia by the ligature, nearly such as is described by Celsus, an operation (continues Scarpa) which a long while since, and for good reasons, was altogether abandoned. Desault himself has put some restrictions to the employment of the ligature, since he observes, that this method does not radically cure the umbilical hernia of children arrived at the age of four years; and that even in the youngest children, a radical cure cannot be effected by the ligature, unless a methodical compression of the navel, by means of a bandage, be kept up immediately after the operation, and for two or three months. It is perhaps to the omission of this last means, that a relapse is to be ascribed in several of the children operated upon by Desault. "*Desault avoit remis en vigueur la ligature tombée en désuétude. Il s'abusoit sur sa valeur; et il n'est pas difficile d'en connoître la cause. Tous les enfans qu'il opéroit à l'Hôtel-Dieu sortoient guéris, et n'y revenoient plus: on regardoit alors comme radicale une guérison momentanée.*"—(*Richerand, Nosographie Chir. t.* 2, *p* 453.) "I have carefully watched (says Scarpa) the immediate effects, and the more or less remote consequences of tying the umbilical hernia, either simply, or by means of a needle and double ligature; and after a considerable number of such cases, I believe I can assert, that *this operation, howsoever performed, is not always exempt from grave and sometimes dangerous accidents. I can also add, that it never procures a truly radical cure, unless the cicatrix, occasioned by it in the umbilical region, be submitted for some months to a methodical and uninterrupted compression. It is not so uncommon as some surgeons pretend, to see arise, after the application of the ligature, a fever attended with symptoms of most violent irritation, and acute sufferings, which cause incessant crying, and sometimes convulsions. The ulcer, which is produced by the detachment of the swelling, is always very large and difficult to heal. Every now and then it becomes painful and emits fungous granulations, even though dressed with dry applications.*

"Latterly it has been explained by a celebrated surgeon (*Palatta Memor. del' Instituto, tom.* 2, *part* 1), that the umbilical vein and the suspensory ligament of the liver being included in the ligature of the umbilical hernia, the inflammation which originates in these parts may, perhaps, in certain cases, be communicated to the liver, so as to put the child's life in great danger. When, in consequence of the ligature, symptoms of violent irritation come on, they are ordinarily attributed to certain individual circumstances, such as extreme sensibility, or a particular disposition to spasm. Hence, it is believed, that they should be considered as exceptions which do not exclude the general rule, and prove nothing against the utility of the operation. But how (says Scarpa) can the surgeon ascertain the existence or nonexistence of these individual dispositions, in the children upon which he is to operate? Assuredly, those subjects in which I have had occasion to notice

the above accidents, enjoyed, before the operation, perfect health in every respect.

"Whatever process be adopted for tying the umbilical hernia, it is evident that the tumour can only be constricted as far as a little way on this side of the aponeurotic ring of the umbilicus, whence it follows, that the integuments must always remain prominent and relaxed for a certain extent, at the front and circumference of this opening. Also, after the separation of the strangulated portion, there necessarily remains under the cicatrix, a portion of the hernial sac, and of the loose integuments which covered it; and as the cicatrix itself never acquires sufficient firmness to resist the impulse of the viscera, which tend to insinuate themselves into the remains of the hernial sac, the hernia sooner or later reappears, and in a short time becomes larger than it was before the operation. If the subject is a little girl, it may be apprehended that the first pregnancy will cause a recurrence of the hernia; for, it is known that during gestation the external cicatrix of the umbilicus is considerably distended, and much disposed to give way."

Scarpa then notices, that "after the separation of the tumour, there always remains between the aponeurotic ring of the navel and the integuments a small cavity formed by the neck of the hernial sac; a cavity into which the viscera begin to insinuate themselves after the operation, so as to hinder the complete contraction of the umbilical ring. The demonstration of what I have advanced is, in some measure, to be found in the old method of operating for the inguinal hernia, not in a strangulated state, by the ligature of the hernial sac and spermatic cord. Most of the herniæ operated upon by this barbarous process were subject to relapses, because, in all probability, the cicatrix was not sufficiently firm to resist the impulse of the viscera, which entered the remains of the hernial sac. In the same manner, after the common operation for the strangulated inguinal hernia, although the cicatrix is formed very near the ring, there is no prudent surgeon who does not advise the patient to wear a bandage the rest of his life, observation having proved that the hernia is still liable to recur.

"The experience of several ages leaves no doubt, that compression alone is an extremely efficacious method of radically curing the umbilical hernia of young subjects. It is attended with no risk, and, provided it be executed with the requisite caution, it is hardly ever necessary to continue it longer than two or three months for the purpose of obtaining a complete cure. On the other side, if it be clearly proved by all that I have been observing, that the ligature never accomplishes a perfect cure without compression, it is manifest, that it cannot be at all advantageous for the children of the poor, since a bandage cannot be dispensed with. It may be said, that, in general, it does not shorten the treatment; for, in the most successful cases, the ulcer caused by it is not healed in less than a month, and, in order to make the cure certain, an exact compression must afterward be kept up, by means of a bandage, two months longer. It has already been stated, that three months are ordinarily sufficient for obtaining a radical cure by the mere employment of a compressive bandage."—(*Scarpa, Traité des Hernies, p.* 344—349.)

M. Girard published a memoir on the umbilical hernia of children, which was read to the Medical Society of Lyons in May, 1811, and the object of which was to recommend compression as an effectual means of cure. The arguments used were very similar to those adduced by Scarpa. In the course of the discussion, M. Cartier affirmed, that he had seen many children operated upon by Desault, who were not cured of their herniæ.—(See *Journ. Gén. de Méd. t.* 41, 1811.)

The subject was afterward taken up by the Medical Society of Paris, and the result of the debate was, that the employment of the ligature ought to be rejected. 1. Because the cure of umbilical herniæ is often accomplished by nature alone. 2. Because compression, either alone or aided by tonic remedies, always succeeds. 3. Because the operation of the ligature deserves the triple reproach of being painful, and not free from danger, if unfortunately a piece of intestine should chance to be included in the ligature; of not succeeding in general, except with the assistance of compression; and of being sometimes uselessly practised, as Desault himself gives us instances of. According to M. Cayol, the insufficiency of the ligature was long since acknowledged by Sabatier, Lassus, Richerand, &c.

The treatment by compression is universally preferred by British surgeons.

UMBILICAL HERNIA IN ADULT SUBJECTS.

This case is to be treated on the principles common to all ruptures. When reducible, the parts should be kept up with a bandage or truss: which plan, however, in grown up persons, affords no hope of a radical cure. Mr. Hey has described some very good trusses for the exomphalos, which are applicable to children, when compression is preferred, as well as to adult subjects. One was invented by the late Mr. Marrison, an ingenious mechanic at Leeds.

"It consists of two pieces of thin elastic steel, which surround the sides of the abdomen, and nearly meet behind. At their anterior extremity they form conjointly an oval ring, to one side of which is fastened a spring of steel of the form represented. At the end of this spring is placed the pad or bolster that presses upon the hernia. By the elasticity of this spring, the hernia is repressed in every position of the body, and is thereby retained constantly within the abdomen. A piece of calico or jean is fastened to each side of the oval ring, having a continued loop at its edge, through which a piece of tape is put, that may be tied behind the body. This contrivance helps to preserve the instrument steady in its proper situation."—(*Practical Obs. in Surgery, p.* 231.) And, in the second edition of the preceding work, another truss for the exomphalos is described, the invention of Mr. England, of Leeds; but, as some account is given of this instrument, with an engraving, in the last editions of the *First Lines of Surgery*, I shall not here repeat the description.

When the exomphalos is irreducible and large, the tumour must be supported with bandages.

It is observed by Scarpa, that the umbilical hernia, and those of the linea alba, are less subject to be strangulated than the inguinal and femoral herniæ; but that, when they are unfortunately affected with strangulation, the symptoms are more intense, and gangrene comes on more rapidly, than in every other species of rupture. If the operations be performed, the event is frequently unfavourable, because it is generally done too late. This practical fact is proved by the experience of the most celebrated surgeons of every age. "*Il est certain* (says Dionis) *que de cette opération il en périt plus qu'il n'en réchappe.*"—*Cours d' Opérations, p.* 98, *ed.* 1777, *avec les notes de La Faye.*) He also adds, that they who have the misfortune to be afflicted with an exomphalos, should rather dispense with their shirt, than a bandage. Heister says nearly the same thing.—(*Instit. Chirurg. t.* 2, *cap.* 94.)

When the omentum alone is strangulated in the exomphalos, or hernia of the linea alba, observation proves that the symptoms are not less intense than when the intestine is also incarcerated. There is this difference, however, that when the omentum alone is strangulated, only nausea occurs, and, if vomiting should likewise take place, it is less frequent and violent than when the bowel itself is strangulated. In the first case, the stools are hardly ever entirely suppressed. The proximity of the stomach is, no doubt, the reason why the strangulation of the omentum in the umbilical hernia occasions far more intense symptoms of sympathetic irritation than the strangulation of the same viscus in the inguinal or crural hernia.

Here the operation is not only always necessary, but urgently required. It is not materially different from that which is practised for strangulated inguinal and crural herniæ; but, in general, it demands greater circumspection on account of the connexion, or intimate adhesions, which frequently exist between the integuments and hernial sac, and also the adhesions which often prevail between the latter part and the omentum which it contains. The situation of the intestine, which is frequently covered by, and enveloped in, the omentum, is another circumstance deserving earnest attention.—(*Scarpa, Traité des Hernies, p.* 361, 362.)

Mr. Pott is not such an advocate as Scarpa for the early performance of the operation in cases of exomphalos: "The umbilical, like the inguinal hernia, becomes the subject of chirurgic operation, when the

parts are not reducible by the hand only, and are so bound as to produce bad symptoms. But though I have in the inguinal and scrotal herniæ advised the early use of the knife, I cannot press it so much in this: the success of it is very rare, and I should make it the last remedy. Indeed, I am much inclined to believe, that the bad symptoms which attend these cases are most frequently owing to disorders in the intestinal canal, and not so often to a stricture made on it at the navel, as is supposed. I do not say that the latter does not sometimes happen; it certainly does; but it is often believed to be the case when it is not.

"When the operation becomes necessary, it consists in dividing the skin and hernial sac in such manner as shall set the intestine free from stricture, and enable the surgeon to return it into the abdomen."—(*Pott on Ruptures.*)

The rest of the conduct of the surgeon is to be regulated by the usual principles.

The division of the stricture is properly recommended to be made directly upwards, in the course of the linea alba.

In consequence of the great fatality of the usual operation for the exomphalos, I think the plan suggested, and successfully practised by Sir A. Cooper in two instances, should always be adopted whenever the tumour is large and free from gangrene; a plan that has also received the high sanction of that distinguished anatomist and surgeon, Professor Scarpa.—(*Traité des Hernies, p.* 362.) Perhaps I might safely add, that when the parts admit of being reduced, without laying open the sac, this method should always be preferred. It consists in making an incision just sufficient to divide the stricture, without opening the sac at all, or, at all events, no more of it than is inevitable.

In umbilical hernia, of not a large size, Sir A. Cooper recommends the following plan of operating: "As the opening into the abdomen is placed towards the upper part of the tumour, I began the incision a little below it, that is, at the middle of the swelling, and extended it to its lowest part. I then made a second incision at the upper part of the first, and at right angles with it, so that the double incision was in the form of the letter T, the top of which crossed the middle of the tumour. The integuments being thus divided, the angles of the incision were turned down, which exposed a considerable portion of the hernial sac. This being then carefully opened, the finger was passed below the intestines to the orifice of the sac at the umbilicus, and the probe-pointed bistoury being introduced upon it, I directed it into the opening at the navel, and divided the linea alba downwards to the requisite degree, instead of upwards, as in the former operation. When the omentum and intestine are returned, the portion of integument and sac which is left falls over the opening at the umbilicus, covers it, and unites to its edge, and thus lessens the risk of peritoneal inflammation, by more readily closing the wound."—(*On Crural and Umbilical Hernia.*)

LESS FREQUENT KINDS OF HERNIA.

The *ventral hernia*, described by Celsus, is not common; it may appear at almost any point of the anterior part of the belly, but is most frequently found between the recti muscles. The portion of intestine, &c. is always contained in a sac, made by the protrusion of the peritoneum. Sir A. Cooper imputes the disease to the dilatation of the natural foramina for the transmission of vessels, to congenital deficiencies, lacerations and wounds of the abdominal muscles or their tendons. In small ventral herniæ, a second fascia is found beneath the superficial one; but, in large cases, the latter is the only one covering the sac.

Herniæ in the course of the linea alba sometimes occur so near the umbilicus, that they are liable to be mistaken for true umbilical ruptures. They may take place either above or below the navel. The first case, however, is more frequent than the second, and the following is the reason of this circumstance, according to the opinion of Scarpa: "The upper half of the linea alba, that which extends from the ensiform cartilage to the umbilicus, is naturally broader and weaker than the lower half, the recti muscles coming nearer and nearer together, as they descend from the navel to the pubes."—(*Scarpa, Traité des Hernies, p.* 333.)

The hernial sac of ruptures at the upper part of the linea alba may contain a noose of intestine and a piece of the omentum, though, in most cases, a portion of the latter membrane alone forms the contents. In some subjects, the linea alba is so disposed to give way, that several herniæ are observed to be formed successively in the interspace between the ensiform cartilage and the umbilicus.

"With respect to the small hernia (says Scarpa) which is considered as formed by the stomach, and concerning which Hoin and Garengeot have written so much (without either of them having related, at least to my knowledge, a single example proved by dissection), it is at least unproved, that it was exclusively formed by this viscus. I do not see why the other viscera, particularly the omentum and transverse colon, might not also contribute to it. In my judgment, it only differs from other hernia of the linea alba, in being situated on the left side of the ensiform cartilage, a situation that must materially influence the symptoms of the case. In fact, whatever may be the viscera which form it, a sympathetic irritation of the stomach is occasioned, that is much more intense than that which ordinarily accompanies umbilical herniæ, those of the lower part of the linea alba, or, in short, all other herniæ, which are more remote from the stomach.—(*Op. cit. p.* 334.)

The following are said to be the circumstances by which the umbilical hernia, and that which occurs in the linea alba near the navel, may be discriminated.

The first, whether in the infant, or the adult, has a roundish neck, or pedicle, at the circumference of which the aponeurotic edge of the umbilical ring can be felt. Whatever may be its size, its body always retains nearly a spherical shape. Neither at its apex, nor its sides, is any wrinkling of the skin, or any thing like the cicatrix of the navel, distinguishable. At some points of the surface of the tumour, the skin is merely somewhat paler and thinner than elsewhere.

On the contrary, the hernia of the linea alba has a neck, or pedicle, of an oval form, like the fissure through which it is protruded. The body of the tumour is also constantly oval. If the finger be pressed deeply round its neck, the edges of the opening in the linea alba can be felt; and if the hernia be situated very near the umbilical ring, the cicatrix of the navel may be observed upon one side of it, which cicatrix retains its rugosity and all its natural appearance; a certain indication that the viscera are not protruded through the umbilical ring.—(*Scarpa, Traité des Hernies, p* 336.)

The distinction which Scarpa has established between the umbilical hernia, properly so called, and those of the linea alba, is not useless in regard to practice. Indeed, when the latter are left to themselves they make much slower progress than the former. On account of their smallness they frequently escape notice, particularly in fat persons, and when situated at the side of the ensiform cartilage. They occasion, however, complaints of the stomach, habitual colics, especially after meals; and unfortunately for the patient, he may be tormented a very long time by these indispositions, before the true cause of them is discovered.

The umbilical hernia may be known, from the earliest period of its formation, by the alteration, which it produces in the cicatrix of the navel, and the rapidity of its increase.

In other respects, these two kinds of herniæ demand the same means of cure; but those of the linea alba, *cæterus paribus*, are more difficult to cure than ruptures at the umbilicus. This is probably owing to the natural tendency which the umbilical ring has to close when the hernia is kept well reduced, while accidental openings in the linea alba have not the same advantage.—(*Scarpa, p.* 340.)

When a common ventral hernia is reduced, it should be kept in its place by means of a bandage or truss. When strangulated, it admits, more frequently than most other cases, of being relieved by medical treatment. If attended with stricture, which cannot otherwise be relieved, that stricture must be carefully divided. Sir A. Cooper recommends the valvular incision and the dilatation to be made, either upwards or downwards, according to the relative situation of the tumour and epigastric artery, which crosses the lower part of the linea semilunaris.

Pudendal Hernia.—This is the name assigned by Sir A. Cooper to the hernia which descends between

the vagina and ramus ischii, and forms an oblong tumour in the labium, capable of being traced within the pelvis as far as the os uteri. He thinks, that this case has sometimes been mistaken for a hernia of the foramen ovale. When reducible, a common female bandage, or the truss used for a prolapsis ani should be worn. A pessary, unless very large, could not well keep the parts from descending, as the protrusion happens so far from the vagina. Sir A. Cooper is of opinion, that, when strangulated, this hernia, in consequence of the yielding nature of the parts, may generally be reduced, by pressing them, with gentle and regular force against the inner side of the branch of the ischium. If not, the warm bath, bleeding, and tobacco clysters, are advised. Were an operation indispensable, the incision should be made in the labium, the lower part of the sac carefully opened, and with a concealed bistoury, directed by the finger, in the vagina, the stricture should be cut directly inwards towards the vagina. The bladder should be emptied both before the manual attempts at reduction and the operation.—(*On Crural Hernia, &c. p.* 64.)

Vaginal Hernia.—A tumour occurs within the os externum. It is elastic but not painful. When compressed, it readily recedes, but is reproduced by coughing, or even without it when the pressure is removed. The inconveniences produced are an inability to undergo much exercise or exertion; for every effort of this sort brings on a sense of bearing down. The vaginal hernia protrudes in the space left between the uterus and rectum. This space is bounded below by the peritoneum, which membrane is forced downwards towards the perineum; but, being unable to protrude further in that direction, is pushed towards the back part of the vagina. In one case, Sir A. Cooper advised the use of a pessary, but the plan was neglected. Probably these cases are always intestinal.

Some herniæ protrude at the anterior part of the vagina.—(*A. Cooper on Crural Hernia, &c. p.* 65, 66.)

Perineal Hernia.—In men, the parts protrude between the bladder and rectum; in women, between the rectum and vagina. The hernia does not project, so as to form an external tumour, and, in men, its existence can only be distinguished by examining in the rectum. In women, it may be detected both from this part and the vagina.

In case of strangulation, perhaps this hernia might be reduced by pressure from within the rectum. An interesting case of perineal hernia, which took place from the peritoneum being wounded with the gorget in lothotomy, is related by Mr. Bromfield.—(*Chirurgical Obs. p.* 264.)

The reducible perineal hernia in women may be kept from descending, by means of a large pessary. Both this kind of rupture and the vaginal may prove very dangerous in cases of pregnancy.—(*See Smellie's Midwifery, case* 5.)

Sacro-rectal Hernia.—In a young infant, where the ossification of the sacrum was incomplete, a protrusion is said to have been met with through an opening in that bone. The possibility of such a case should be remembered, in order that the disease may not be mistaken for spina bifida.—(*See Journ. of Foreign Med. Nv.* 16, *p.* 616.)

Thyroideal Hernia, or *Hernia Foraminis Ovale.*—In the anterior and upper part of the obturator ligament, there is an opening, through which the obturator artery, vein, and nerve proceed, and through which, occasionally, a piece of omentum or intestine is protruded, covered with a part of the peritoneum, which constitutes the hernial sac.

In the case which Sir A. Cooper met with, the hernia descended above the obturatores muscles. The os pubis was in front of the neck of the sac; three-fourths of it were surrounded by the obturator ligament; and the fundus of the sac lay beneath the pectineus and abductor brevis muscles. The obturator nerve and artery were situated behind the neck of the sac, a little towards its inner side. This species of hernia can only form an outward tumour, when very large. Garengeot, however, met with an instance, in which there was not only a swelling, but one attended with symptoms of strangulation; he reduced the hernia, which went up with a guggling noise; the symptoms were stopped, and stools soon followed.

The hernia of the foramen ovale, when reducible, must be kept up with a suitable truss; and if it were strangulated, and not capable of relief from the usual means, an operation would be requisite, though attended with difficulties. The division of the obturator ligament and mouth of the sac should be made inwards to avoid the obturator artery. If this vessel, however were to arise in common with the epigastric artery, it would be exposed to injury by following this plan.—(See *Garengeot in Mem. de l'Acad. de Chir. t.* 1. *A. Cooper on Crural Hernia, &c. p.* 70.)

Cystocele.—As Mr. Pott observes, "the urinary bladder is also liable to be thrust forth from its proper situation, either through the opening in the oblique muscle, like the inguinal hernia, or under Poupart's ligament, in the same manner as the femoral.

"This is not a very frequent species of hernia, but does happen, and has as plain and determined a character as any other.

"It has been mentioned by Bartholin, T. Dom. Sala, Platerus, Bonetus, Ruysch, Petit, Mery, Verdier, &c. In one of the histories given by the latter, the urachus, and impervious umbilical artery on the left side were drawn through the tendon into the scrotum, with the bladder; in another he found four calculi.

"Ruysch gives an account of one complicated with a mortified bubonocele. Petit says, he felt several calculi in one, which were afterward discharged through the urethra.—(See also *J. G. F. John de insolitâ Calculi Ingentis per Scrotum Exclusione. Wittenberg*, 1750.)

"Bartholin speaks of T. Dom. Sala as the first discoverer of the disease, and quotes a case from him, in which the patient had all the symptoms of a stone in his bladder; the stone could never be felt by the *sound*, but was found in the bladder (which had passed into the groin) after death.

"As the bladder is only covered in part by the peritoneum, and must insinuate itself between that membrane and the oblique muscle, in order to pass the opening in the tendon, it is plain that the hernia cystica can have no sac, and that, when complicated with a bubonocele, that portion of the bladder which forms the cystic hernia must lie between the intestinal hernia and the spermatic cord, that is, the intestinal hernia must be anterior to the cystic.

"A cystic hernia may, indeed, be the cause of an intestinal one; for when so much of the bladder has passed the ring, as to drag in the upper and hinder part of it, the peritoneum which covers that part must follow, and by that means a sac be formed for the reception of a portion of gut or caul. Hence the different situation of the two herniæ in the same subject.

"While recent, this kind of hernia is easily reducible, and may, like the others, be kept within by a proper bandage; but when it is of any date, or has arrived to any considerable size, the urine cannot be discharged, without lifting up, and compressing the scrotum: the outer surface of the bladder is now become adherent to the cellular membrane, and the patient must be contented with a suspensory bag.

"In case of complication with a bubonocele, if the operation becomes necessary, great care must be taken not to open the bladder instead of the sac, to which it will always be found to be posterior. And it may also sometimes by the inattentive be mistaken for a hydrocele, and by being treated as such may be the occasion of great or even fatal mischief."—(*Vol.* 2.)

The cystocele is always easily distinguishable by the regular diminution of the swelling, whenever the patient makes water.

Verdier and Sharp have accurately described the cystocele. Pott has offered two cases, which fell under his observation.—(*Vol.* 3.) Pipelet le Jeune mentions a cystic hernia in perinæo, and several cases of its occurrence in the female.—(*Acad. de Chir. t.* 4.) Pott cut into one cystocele by mistake. Mention is made (*Edin. Surg. Journ. vol.* 4, *p.* 512) of a cystic hernia, which protruded between the origins of the levator ani, and obturator internus muscles: the tumour made its appearance in the pudendum of an old woman. Much additional information, respecting the cystocele and its various forms, is contained in the second volume of the *First Lines of Surgery*, *p.* 49, *&c. ed.* 4, accompanied with references to all the most interesting writers on the subject. An instance of protrusion of the bladder through a wound, caused by a bullock's horn, is recorded by Larrey.—(*Mém. de Chir. Mil. t.* 4. *p.* 289.)

Ischiatic Hernia.—This disease is very rare. A case, however, which was strangulated, and undiscovered till after death, is related in Sir A. Cooper's second part of his work on hernia. It was communicated by Dr. Jones, so celebrated for his book on hemorrhage. The disease happened in a young man, aged 27. On opening the abdomen, the ileum was found to have descended on the right side of the rectum into the pelvis, and a fold of it was protruded into a small sac, which passed out of the pelvis at the ischiatic notch. The intestine was adherent to the sac at two points: the strangulated part, and about three inches on each side, were very black. The intestines towards the stomach were very much distended with air, and here and there had a livid spot on them. A dark spot was even found on the stomach itself just above the pylorus. The colon was exceedingly contracted, as far as its sigmoid flexure. A small orifice was found in the side of the pelvis, in front of, but a little above, the sciatic nerve, and on the fore part of the pyriformis muscle. The sac lay under the glutæus maximus muscle, and its orifice was before the internal iliac artery, below the obturator artery, but above the vein. Sir A. Cooper remarks, that a reducible case might be kept up with a spring-truss; and that, if an operation were requisite, the orifice of the sac should be dilated directly forwards.—(*On Crural Hernia, &c. p.* 73.) For a further account of the ischiatic hernia, and references to the most interesting works on the subject, see *First Lines of Surgery, vol.* 2, *p.* 84, *&c.*

Phrenic Hernia.—The abdominal viscera are occasionally protruded through the diaphragm, either through some of the natural apertures in this muscle, or deficiencies, or wounds and lacerations in it. The second kind of case is the most frequent: Morgagni furnishes an instance of the first. Two cases, related by Dr. Macauley in *Med. Obs. and Inq. vol.* 1, two more detailed in the *Medical Records and Researches*, and two others published by Sir A. Cooper, are instances of the second sort; and another case has been lately recorded by the latter gentleman, affording an example of the third kind. A laceration of the diaphragm by fractured ribs, has produced a hernia. A case of this kind was dissected by Mr. Travers, at Guy's Hospital.—(*Med. Chir. Trans. vol.* 6, *p.* 375.) In this last volume may also be found the particulars of an interesting example, in which a considerable part of the large curvature of the stomach was protruded through a fissure of the diaphragm. The accident was unattended with any fracture of the ribs, and was caused by the upsetting of a stage-coach, on which the patient was an outside passenger. Before death, he vomited up a large quantity of blood, and a small semicircular aperture was discovered on dissection in the lower part of the strangulated portion of the stomach. —(*P.* 378, 379.) See also *B. Stchelin, Tentamen, Med. quod ventriculum, qui in thoracem migraverat, &c., describit*, 1721 (*in Halleri Disp. Anat. tom.* 6. *p.* 675). Hildanus, Paré, Petit, Schenck, &c., also mention cases of phrenic hernia. The disease is quite out of the reach of art.

Mesenteric Hernia.—If one of the layers of the mesentery be torn by a blow, while the other remains in its natural state, the intestines may insinuate themselves into the aperture, and form a kind of hernia. The same consequence may result from a natural deficiency in one of these layers. Sir A. Cooper records a case, in which all the small intestines, except the duodenum, were thus circumstanced. The symptoms during life were unknown.—(*On Crural Hernia, &c., p.* 82.)

Mesocolic Hernia.—So named by Sir Astley Cooper, when the bowels glide between the layers of the mesocolon. A specimen of this disease is preserved at St. Thomas's Hospital.

Every surgeon should be aware, that the intestines may be strangulated within the abdomen from the following causes: 1. Apertures in the omentum, mesentery, or mesocolon, through which the intestine protrudes. 2. Adhesions, leaving an aperture, in which a piece of intestine becomes confined. 3. Membranous bands at the mouths of hernial sacs, which, becoming elongated by the frequent protrusion and return of the viscera, surround the intestine, so as to strangulate them within the abdomen, when returned from the sac.—(See *A. Cooper on Crural Hernia, &c., p.* 85.)

Pott remarks, that "Ruysch gives an account of an impregnated uterus being found on the outside of the abdominal opening; and so do Hildanus and Sennertus. Ruysch also gives an account of an entire spleen having passed the tendon of the oblique muscle. And I have myself seen the ovaria removed by incision, after they had been some months in the groin."—(*Vol.* 2.)

[Two formidable cases of *Congenital Umbilical Hernia* have occurred recently in New-York, both of which were irreducible, and operated on by Professor Mott, within two hours after birth. The first of these proved fatal, but the other recovered.

In both of these cases, all the smaller intestines, the mesentery, the caput coli, and transverse arch, with the descending colon to the sigmoid flexure, were contained in the umbilical cord. The umbilical aperture was greatly enlarged, and the component parts of the tumour could be distinctly recognised through the translucent coverings. The children were full-sized and otherwise healthy.

The operation in each case was performed in the following manner, as they were very similar in extent. The intestines were exposed by cutting cautiously through the envelopes, consisting of transparent membrane, which was a task of great delicacy. The arteries and vein were each tied with small ligatures, about half an inch from the umbilical aperture. The quantity of intestines protruded, being too great for reduction by the natural opening, this was enlarged upwards in the linea alba to the extent of half an inch, by which means all the protruded parts were returned into the abdomen, and each intestine placed in situ. The opening was then closed by the interrupted suture and adhesive plaster.

The adhesions were so strong and numerous in the first case, and the intestines so much contracted, as to afford but little hope of succeeding in procuring a discharge through them. This case proved fatal, as no free discharge could be obtained through the bowels. The vomiting, which had occurred before the operation, continued, and the child died in about twenty-four hours.

In the second case the adhesions were not so extensive, and the intestines were but little contracted. This child recovered without one untoward symptom, and is perfectly well.—*Reese.*]

HERNIA CEREBRI. *Fungus Cerebri. Encephalocele.*) There are two principal kinds of hernia cerebri: one presents itself in young infants, before the ossification of the skull is completed; the other takes place after the destruction of a part of the skull by the operation of the trephine, accidental violence, or disease.

The congenital hernia cerebri of infants occurs, however, in two very different forms: in one, it is covered by the scalp; in the other, the corresponding integuments of the head, and sometimes even the dura mater, are deficient.

The common encephalocele, met with in new-born children, seems to originate from the imperfect ossification of the skull, especially in the situation of the fontanella and sutures. This case is characterized by a soft swelling, of an equal round shape, which is attended with a pulsation corresponding to that of the pulse: it yields and disappears under pressure, offers no alteration in the colour of the skin, and is circumscribed by the margin of the defective portion of the skull.—(*Ferrand, in Mém. de l'Acad. de Chir. t.* 13, 12*mo. p.* 102.) In general, the mental faculties are not affected; and we read of one example, in which a patient had such a hernia cerebri thirty-three years, without his intellects ever having been impaired during the whole of that period.—(*Op. cit. t.* 5, 4*to. p.* 863.)

It is tolerably well established, that the congenital hernia cerebri, which arises from the incomplete ossification of the skull, and is covered by the scalp, ought to be treated by the application of constant, yet moderate, pressure. M. Salleneuve communicated to the Royal Academy of Surgery in France an example of the good effects of this treatment, which reduces the size of the tumour, and accomplishes a perfect cure as soon as the ossification is completed. M. Salleneuve put a piece of thin sheet lead, properly covered with soft linen, under the child's cap, to which it was sewed in a suitable situation, and the degree of pressure was increased, or lessened, according as circumstances required, by tightening or loosening the cap.—(*Op. cit. p.* 103, *t.* 13, *ed.* 12*mo.*)

The experience of Callisen also confirms the fact that hernia cerebri, when of moderate size, may be cured by the foregoing method, the aperture becoming gradually closed. But he adds, that large tumours of this description, especially when situated about the occiput, scarcely admit of any means of relief, except the employment of some contrivance to protect them from external injury.—(*Callisen, System. Chir. Hodiernæ, vol.* 2, *p.* 513, 514, *ed.* 1800.)

When the ossification of the sutures in children is late, the cerebellum, as well as the cerebrum, is liable to protrusion. In 1813, two such cases occurred at Paris. In one, Professor Lallement mistook the disease for a common tumour, and commenced an operation for its removal, when, after making some of the necessary incisions, his proceedings were stopped by his seeing the white silvery colour of the dura mater, and that the swelling came out of an aperture in the occipital bone. The day after the operation the child was seized with violent pain in the head, had a hard pulse, prostration of strength, vomiting, &c., and died in the course of a week. On dissection, a part of the tentorium, and an elongation of the two lobes of the cerebellum, about as large as a nut, were found in the protruded sac of the dura mater. Several abscesses were also discovered in the substance of the cerebellum. The other example fell under the observation of M. Baffos, principal surgeon to the Hôpital des Enfans. Upon the death of the child, the dissection evinced similar appearances.—(*Richerand, Nosographie Chir. t.* 2, *p.* 319, *ed.* 4.)

Such facts should teach the surgeon to be particularly cautious in ascertaining the nature of tumours about the back part of the head, before he ventures to attempt their removal.

The second kind of congenital encephalocele is that in which not only large portions of the cranium, but also more or less of the integuments of the head, are deficient. It is rather to be regarded as a malformation, than a disease, and, indeed, in most instances, the infants are stillborn. The case sometimes consists of the protrusion of most of the brain through the inferior and posterior fontanellæ, so that the child is born with a largish bag, on the back of its head, hanging down over the posterior part of the neck. Several specimens of these malformations, taken from infants born in the Hospice de la Maternité, are preserved in the museum of the Faculté de Médecine at Paris.—(*Richerand, Nosogr. Chir. t.* 2, *p.* 316, *ed.* 4.) In the year 1810, a remarkable case of this last description of congenital hernia cerebri was published by Dr. Burrows. "The whole of the forehead, summit, and a great part of the occiput, were deficient; and in lieu of them, a substance projected of a light mulberry colour, and of the mushroom form, except that it was proportionably broader. From the deficiency of bone, the eyes appeared to project much more than usual. The child lived six days without either taking sustenance, or having any evacuation." On dissection, the scalp, the os frontis, the parietal, and a great part of the occipital bones, were wanting. Through the parts, at which these bones were deficient, the cerebrum projected, exhibiting its usual convolutions. It was covered with the pia mater; was of a mulberry colour; appeared to be more vascular than the pia mater usually is; and the edge of the scalp adhered to the neck of the tumour. The cerebellum was not more than one-fourth of its usual size; for the posterior part of the os occipitis was much nearer to the sella turcica than natural. The child was destitute of the power of voluntary motion, and all the secretions appeared to be stopped.—(See *Med. Chir. Trans. vol* 2, *p.* 52.)

The most interesting species of hernia cerebri to the practitioner, is that which sometimes arises after the removal of a portion of the skull by the trephine, or the destruction of part of it by disease. Various examples of this disease are recorded in the Memoirs of the French Academy of Surgery, and I have myself seen many instances of it. Although the case has

attracted considerable notice, modern surgeons are far from entertaining settled opinions concerning the exact nature of the tumour.

In one example, recorded by Mr. Abernethy, the hernia cerebri arose on the tenth day after trephining, and was as large as a pigeon's egg. The pia mater, covering it, was inflamed; and a turbid serum was discharged at the sides of the swelling, from beneath the dura mater. On the eleventh day, the tumour was as large as a hen's egg, smooth, and ready to burst. The man died the next day. On examination, the swelling was found still larger, and of a dark colour, with an irregular granulated surface. This appearance was owing to coagulated blood, which adhered to its surface, as the part had bled so much, that the patient's cap was rendered quite stiff with blood. The pia mater was in general much inflamed, and, as well as the dura mater, was deficient at the place of the tumour. The deeper part of the swelling seemed to consist of fibrous coagulated blood, and it was found to originate about an inch below the surface of the brain.

Mr. Abernethy explains the formation of the disease as follows: "In consequence of the brain being injured to some depth beneath the surface, disease of the vessels and consequent effusion of the blood had ensued: the effusion was, for a time, restrained by the superincumbent brain and its membranes; but, these gradually yielding to the expansive force exerted from within, and at last giving way altogether, the fluid blood oozed out and congealed upon the surface of the tumour." An organized fungus can hardly be produced so rapidly as these tumours are formed.—(*On Injuries of the Head, in Surgical Works, vol.* 2, *p.* 53.)

On the contrary, Mr. C. Bell declares, that the swelling is vascular and organized.—(*Operative Surgery, vol.* I.)

Dr. John Thomson also entertains a different opinion from that of Mr. Abernethy, respecting the mode in which these herniæ cerebri are formed: but I question whether he may not have confounded with the disease now under consideration, fungous tumours of the dura mater. At least, some of the cases to which he alludes, as a reason for his sentiment concerning their mode of formation, must have been the disease so well described by M. Louis.—(See *Dura Mater.*) The reader, however, must judge for himself from the following passage: "In a considerable number of those who had the cranium severely contused, or fractured by musket-balls (says Dr. Thomson), fungous growths took place through the openings, which had been made at first by the ball, or afterward by the trepan. These growths, I am inclined to believe, are the consequence of a contusion of the substance of the brain, and of the membranes that cover it, which gives rise to the formation of a new organized substance, different in its texture from brain; and are not, as some late writers would endeavour to persuade us, simply protrusions of the brain, resulting from the removal of the natural resistance, which is made to them by the dura mater and cranium. *I have known instances of substances, similar to these growths, forming on the surface of the brain, immediately under the place where the cranium had received a contusion, in cases in which the trepan had not been applied, or any portion of the cranium removed.*

"Fungus of the brain, in the greater number of instances, in which we had an opportunity of observing it, was accompanied either with stupor or paralysis, and other symptoms of compressed brain. In a fracture of the vertex of the cranium, produced by a musket-ball, and followed by a fungus of the brain, the paralysis took place in the lower extremities. In a case of wound, made by a musket-ball on the right side of the forehead, and in which spiculæ of bone had been driven in upon the brain, a large fungus protruded. The formation of this fungus was followed by slow pulse, stupor, dilated pupils, slight strabismus, and distortion of the mouth. In the progress of this case, escharotics were applied to the fungus, portions of it were torn off by the patient, and all of it that was exterior to the cranium was twice pared off by the knife, with an apparent alleviation, rather than aggravation, of the symptoms. On the death of this patient, nearly the whole of the right hemisphere of the brain was found converted into a soft pulpy mass. The left hemisphere was not changed in structure, though much vascular turgescence appeared on its surface."—(See *Dr. J. Thomson's Report of Observations made in the Military Hospitals in Belgium, p.* 57, 58.)

From the investigations of Mr. Stanley, the fact is placed beyond all doubt, that a part of the brain occasionally constitutes the substance of herniæ cerebri and he thus confirms the opinion formerly entertained upon this point by Quesnay and Louis. Thus, in the first case which Mr. Stanley has recorded, "the whole tumour was sliced off with a scalpel. During the operation, the boy gave no manifestation of positive pain, although not unconscious of what we were doing. Considerable hemorrhage took place from the surface of the brain, exposed by the removal of the tumour, the blood being thrown with great force, and to a considerable distance, from numerous vessels, which were attempted to be secured, but ineffectually by ligatures. After a short time, however, the bleeding ceased. On examination of the part, which had been cut off, its exterior was found to consist merely of a layer of the coagulated blood; the rest of the mass was brain, possessing a natural appearance, the distinction between the cortical and medullary matter being readily seen, with the convolutions and pia mater dipping down between them." In the dissection after death, "all that part of the dura mater adjacent to the ulcerated aperture, through which the brain had protruded, was black, sloughy, and much thickened. The exposed surface of the brain, from which the portion had been cut off, exhibited a softened and broken-down texture; a state of disorganization, which extended deep into its substance. About an ounce of fetid and dark-coloured fluid was found between the dura mater and arachnoid membrane. Several small effusions of blood were met with, both between the membranes and in the substance of the brain. The arachnoid membrane was thickened and opaque over each hemisphere. The vessels on the surface, and in the substance of the brain, were remarkably free from blood. The lateral ventricles were large, and filled with transparent fluid, and there was some found between the membranes at the basis, so that, altogether, the quantity from these two sources was very considerable."—(See *Med. Chir. Trans. vol.* 8, *p.* 15—17.) In another dissection, a considerable quantity of pus was found on the arachnoid membrane, on each side of the falx.—(*P.* 27.) In most of the cases of hernia cerebri, which I have seen, the patient was at first more or less sensible, but labouring under severe nervous agitation. The stupor, paralysis, and other symptoms of compressed brain, noticed by Dr. J. Thomson, did not take place till the latter stage of the disease, and then convulsive twitches of the muscles and strabismus occasionally came on.—(See *Med. Chir. Trans. p.* 26.) The disease is usually attended with great frequency of the pulse.

With regard to the cause of the protrusion, it is a subject very difficult of explanation, because if the origin of the tumour depended simply on the removal of a portion of the skull, or on any changes of the dimensions of the brain in expiration, the effect would always follow such causes, and prevail in all patients. From the particulars of the dissections, performed by Mr. Abernethy and Mr. Stanley, and those referred to by Dr. J. Thomson, it is clear, that the hernia cerebri is a disease connected with deep-seated changes throughout a great part of the brain.—(See also *Larrey. Mém. de Chir. Mal. t.* 4, *p.* 206.) The substance of this organ is found more or less pulpy and disorganized; and after death large effusions of serum, and even sometimes of blood, and purulent matter, are observed. These appearances leave no doubt of the disease being associated with inflammatory action within the head. It is highly probable, therefore, that a hernia cerebri is only produced when these deep-seated changes are conjoined with the removal of bone. The changes alluded to may be supposed to cause an increase in the general contents of the skull, and thus a disposition to protrusion, as rapid as the serum and other fluids are effused. This statement, however, can only be received as an hypothesis, because we find, that in one of the dissections, described by Mr. Stanley, "there existed a considerable space between the upper surface of the right hemisphere, all around the situation of the protrusion, and the internal surface of the dura mater, while, in every other part, the brain and dura

mater were in close contact."—(See *Med. Chir. Trans. vol.* 8, *p.* 27.) Now, the idea of an empty space within the cranium is rather inconsistent with the supposition, that the brain is thrust out, in consequence of changes, which augment the quantity of the general contents of the skull, unless such space were filled with air, that had no external communication.

When the bad symptoms disappear, on the tumour being no longer confined by the dura mater, some practitioners deem it best to interfere as little as possible, and let the tumour drop off in pieces.—(See *Edinb. Med. Comment. vol.* 1, *p* 98; *Med. Museum, vol.* 4, *p.* 463.) The mildest dressings are to be employed; but whether the protrusion should be resisted by pressure or not seems unsettled.

When the tumour acquires considerable size, it may be pared off with a knife, as was done by Mr. Hill, in several instances, with success.—(*Cases in Surgery*, 8*vo. Edinb.* 1772.)

In one of the cases published by Mr. Stanley, the patient, a boy about eleven years of age, recovered after the upper part of the tumour had been pared off, and some of the removed substance was found to consist decidedly both of cortical and medullary substance. In this instance, the reproduction of the tumour was checked by firm pressure with graduated compresses and a bandage. The protruded brain gradually lost its natural colour: it acquired a light yellow appearance, was split into several portions, and a very fetid odour exhaled from it. Its substance daily became softer, ultimately acquiring almost a semi fluid state, and, in this condition, the whole mass gradually wasted away. *Fresh granulations arose to fill up the vacancy, and they were manifestly produced from the exposed substance of the brain.* Compression being continued, the part now quickly healed up.—(See *Med. Chir. Trans. p.* 20, 21.) In a third case, the part of the tumour cut off consisted entirely of cortical and medullary substance, quite healthy in its appearance (*p.* 24); and subsequently granulations were formed from the exposed surface of the brain. The case, however, had a fatal termination. By the removal of the swelling, and the use of compression, one cure was effected by Mr. Pring.—(See *Edinb. Med. and Surgical Journ. vol.* 9.)

Richerand affirms, indeed, generally, that when the brain is exposed, in consequence of an injury of the head, the encephalocele should be cut down with a knife, and repressed by gentle compression.—(See *Nosogr. Chir. t.* 2, *p.* 318, *ed.* 4.)

Sir A. Cooper is also an advocate for pressure, made with adhesive plaster; and a compress of lint wet with liquor calcis: his aim is to reduce the swelling to a level with the bone, when, he says, the scalp will heal over it.—(*Lectures, vol.* 1, *p.* 317.)

The cases published by Mr. Stanley are rather favourable to the employment of pressure, inasmuch as it appeared evidently to check the protrusion, and was mostly borne without inconvenience.

The idea, however, that when the brain protrudes through the dura mater, pressure can effect its return, is, as Mr. Stanley judiciously observes, quite untenable.—(*Med. Chir. Trans. vol.* 8, *p.* 36.)

Quesnay mentions an instance in which a patient tore off the protruded mass himself, and the cavity healed up.—(*Mém. de l'Acad. de Chir. t.* 1.) Van Swieten relates a case in which the swelling was repeatedly removed with a ligature, and a cure ensued.—(*Comment. t.* 1, *p.* 440.) The danger of applying styptics and irritating applications is shown by Hildanus (*Obs.* 14), and Mr. Hill (*p.* 198).

Baron Larrey considers the treatment by excision, pressure, and spirituous applications hurtful and dangerous: his advice is merely to apply to the swelling a pledget of slightly camphorated oil of chamomile; to have recourse to cooling aperient beverages; to remove all kinds of irritation; to exclude the air; and apply the dressings with great gentleness. By these means, the only case which Larrey ever saw recover was saved, and in it the tumour was small.—(*Mém. de Chir. Mil. t.* 4, *p.* 206.)

One would suppose that cases of this kind must generally require the employment of every thing at all likely to keep off and diminish inflammation of the brain. *Quesnay sur la Multiplicité des Trépans, in Mém. de l'Acad. Royale de Chirurgie, t.* 2, *p* 25. 56, *edit.* 12*mo.* *M. Corvin's Dissert. in Haller's Disputat. Chir. vol.* 2. *Mémoire sur l'Encephalocele, par M. HERNIA HUMORALIS. An inflammation of the testicle, especially when produced by irritation in the urethra, gonorrhœa, the use of bougies, &c. As the term is founded upon the old and now exploded doctrine of the translation of humours from one part to another, the sooner its employment is abandoned the better. The case is considered under the word *Testicle.*

[It would seem from this reference to the word "Testicle," and from the entire omission of the article, contained in the former editions of the dictionary, on the Hernia Humoralis, that Mr. Cooper designed to give this subject a special notice under the word "Testicle." The reader will be surprised to find that he has entirely overlooked this his obvious design; for under that word this disease is only mentioned once, and that incidentally. As Mr. Cooper doubtless had good reasons for considering this among the other diseases of the testicle, and its omission there is the effect of accident, I have concluded to supply the omission under that word, and leave the reference in this place as I find it. I hope in this particular I shall comply with the author's original intention.—*Reese.*]

HERPES. (From ἕρπω to creep.)

Nothing could be more confused and undefined than the idea conveyed by the term *herpes*, as generally employed by medical men until a few years ago. In fact, numerous cutaneous diseases, of the most opposite kinds, but which had a tendency to creep or spread slowly were designated as specimens of herpes. Thus, when I first entered the profession, it was common for some of the most eminent surgeons in London frequently to call noli me tangere, or lupus, herpes of the nose; and to apply the same term to tinea capitis, or the porrigo favosa.

Happily, this vague mode of regarding diseases of the skin is beginning to give way to the judicious distinctions proposed by the late Dr. Willan, and so ably perfected by Dr. Bateman. The appellation *herpes* is limited by these physicians "to a vesicular disease, which in most of its forms passes through a regular course of increase, maturation, and decline, and terminates in about ten, twelve, or fourteen days. The vesicles arise in distinct but irregular clusters, which commonly appear in quick succession, and they are set near together, upon an inflamed base, which extends a little way beyond the margin of each cluster. The eruption is preceded, when it is extensive, by considerable constitutional disorder, and is accompanied with a sensation of heat and tingling, sometimes with severe deep-seated pain, in the parts affected. The lymph of the vesicles, which is at first clear and colourless, becomes gradually milky and opaque, and ultimately concretes into scabs: but in some cases a copious discharge of it takes place, and tedious ulcerations ensue. The disorder is not contagious in any of its forms."—(See *Bateman's Practical Synopsis of Cutaneous Diseases, p.* 221, 222, *ed.* 3.) This author notices six species of the complaint: viz. herpes phlyctænodes; herpes zoster; herpes circinatus; herpes labialis; herpes præputialis; and herpes iris.

As most of these cases more properly belong to the physician than surgeon, I shall briefly describe three of them.

According to Dr. Bateman, the *herpes zoster*, or *skingles*, is mostly preceded for two or three days by

languor and loss of appetite, rigours, headache, sickness, and a frequent pulse, together with a scalding heat and tingling in the skin, and shooting pains through the chest and epigastrium. Sometimes, however, the precursory febrile symptoms are very slight. Upon some part of the trunk several red patches occur, of an irregular form, at a little distance from each other, upon each of which numerous small elevations appear clustered together. These, if examined minutely, are found to be distinctly vesicular; and in the course of twenty-four hours they enlarge to the size of small pearls, and are perfectly transparent, being filled with a limpid fluid. For three or four days fresh clusters continue to arise, always extending themselves nearly in a line with the first, towards the spine at one end, nd towards the linea alba at the other. While the new clusters are appearing, the vesicles of the first lose their transparency, and, on the fourth day, acquire a milky or yellowish hue, which is soon followed by a bluish or livid colour of the basis of the vesicles, and of the contained fluid. They now become somewhat confluent, and flatten or subside. About this time they frequently break and discharge, for three or four days, a serous fluid, which at length concretes into thin dark scabs. These fall off about the twelfth or fourteenth day, leaving the surface of the subjacent skin in a red and tender state; and when the ulceration and discharge have been considerable, numerous cicatrices or pits are left. All the clusters go through a similar series of changes.

Young persons, from the age of twelve to twenty-five, are most frequently affected; although aged persons are not altogether exempt from the complaint, and suffer severely from the pain of it. Summer and autumn are the seasons in which it is most common. Sometimes it supervenes to bowel complaints, and the chronic pains remaining after acute pulmonary diseases. In the treatment, Dr. Bateman thinks gentle laxatives and diaphoretics, with occasional anodynes, when the severe deep-seated pains occur, all that is necessary. No external application is requisite, unless the vesicles be abraded by the friction of the clothes, which are then liable to adhere to the parts: in this case, a little simple ointment may be interposed. For a fuller account, see *Bateman's Pract. Synopsis*, p. 226, &c.

Herpes circinatus, or *ringworm*, makes its appearance in small circular patches, in which the vesicles arise only round the circumference: these are small, with moderately red bases, and contain a transparent fluid, which is discharged in three or four days, when little prominent dark scabs form over them. The central area in each vesicular ring is at first free from any eruption; but the surface becomes somewhat rough, and of a dull red colour, and throws off an exfoliation, as the vesicular eruption declines, which terminates in about a week with a falling off of the scabs. A succession of these vesicular circles usually arises on the face and neck, or arms and shoulders, thus protracting the case for two or three weeks.

The itching and tingling, which are the only inconveniences of the affection, may be relieved by the application of the popular remedy, ink, solutions of the salts of iron, copper, zinc, borax, alum, &c. Some additional interesting observations on other forms of the herpes circinatus may be found in Dr. Bateman's Synopsis, from which I have extracted the few preceding particulars.

Herpes præputialis. This local variety of herpes was not noticed by Dr. Willan, and we are indebted to Dr. Bateman for a description of it. The complaint begins with extreme itching, and with some sense of heat in the prepuce, on which one or two red patches occur, about the size of a silver penny. Upon these are clustered five or six minute transparent vesicles. In twenty-four or thirty hours the vesicles enlarge, become of a milky hue, and lose their transparency; and on the third day they are coherent, and have almost a pustular appearance. If the eruption is seated on that surface of the prepuce which is next the glans, so that the vesicles are kept moist, they commonly break about the fourth or fifth day, and form a small ulceration upon each patch. This discharges a little turbid serum, and has a white base, with a slight elevation at the edges; and by an inaccurate or inexperienced observer it may readily be mistaken for chancre, more especially if any escharotic has been applied, which produces irritation, and a deep-seated hardness like that of a true chancre. If not irritated, the slight ulceration begins to heal about the ninth or tenth day. When the patches occur on the outside of the prepuce, the duration of the eruption is shorter, and ulceration does not actually take place.

In the treatment, Dr. Bateman recommends the avoidance of all stimulating, and moist, or unctuous applications; and if the complaint be within the prepuce, he advises the interposition of a little bit of dry lint between the sore and the glans.

As this gentleman has truly remarked, this case is particularly deserving of notice, because it has often been considered and treated as a chancre.

For a great deal more valuable information respecting herpes, I beg leave to refer the reader to the publications of Drs. Willan and Bateman, and also to the article *Herpes*, written by this last able physician for Dr. Rees's Cyclopædia.

HORDEOLUM. (Dim. of *hordeum*, barley.) A little tumour on the eyelid, resembling a barley-corn. *A stye*. As Scarpa remarks, the stye is strictly only a little boil, which projects from the edge of the eyelids, frequently near the great angle of the eye. Like the furunculus, it is of a dark-red colour, much inflamed, and a great deal more painful, than might be expected, considering its small size. The latter circumstance is partly owing to the vehemence of the inflammation, and partly to the exquisite sensibility and tension of the skin covering the edge of the eyelids. On this account the hordeolum very often excites fever and restlessness in delicate, irritable constitutions; it suppurates slowly and imperfectly; and, when suppurated, has no tendency to burst.

The stye, like other furunculous inflammations, forms an exception to the general rule, that the best mode in which inflammatory swellings can end is resolution. For, whenever a furunculous inflammation extends so deeply as to destroy any of the cellular substance, the little tumour can never be resolved, or only imperfectly so. This event, indeed, would rather be hurtful, since there would still remain behind a greater or smaller portion of dead cellular membrane; which, sooner or later, might bring on a renewal of the stye in the same place as before, or else become converted into a hard indolent body, deforming the edge of the eyelid.

The resolution of the incipient hordeolum may be effected in that stage of it in which the inflammation only interests the skin, and not the cellular substance underneath, as is the case on the first appearance of the disease. Now repellent cold applications are useful, particularly ice. But when the hordeolum has affected and destroyed any of the cellular membrane underneath, every topical repellent application is absolutely useless, and even hurtful; and the patient should have recourse to emollient anodyne remedies. The hordeolum and eyelids should be covered with a warm soft bread and milk poultice, which ought to be renewed very often. When a white point makes its appearance on the apex of the little tumour, Scarpa says, the surgeon should not be in a hurry to let out the small quantity of serous matter, which exists between the skin and dead portion of cellular membrane. It is better that he should wait till the skin within this white point has become somewhat thinner, so as to burst of itself, and give ready vent, not merely to the little serous matter, but to all the dead cellular membrane which constitutes the chief part of the disease. When the contents of the little tumour are slow in making their way outwards, through the opening, the surgeon, gently compressing the base of the stye, ought to force them out. After this, all the symptoms of the disease will disappear, and the cavity, left by the dead cellular membrane in the centre of the little tumour, will be found quite filled up and healed, in the course of twenty-four hours.

Sometimes, though seldom, this process of nature, destined to detach the dead from the living cellular membrane, only takes place incompletely, and a small fragment of yellow dead cellular substance still continues fixed in the cavity, and hinders the cure. In this circumstance, the further employment of emollient poultices is of little or no service. The surgeon should dip the point of a camel-hair pencil in sulphuric acid, and touch the inside of the stye with it, one or more times, until the sloughy cellular membrane comes away. After this, the small cavity remaining will soon close. Should the eyelid continue afterward a little swollen

and œdematous, this affection may be removed by applying the lotio plumbi acet., containing a little spirit of wine. Some persons are often annoyed with this disease. According to Scarpa, this is most frequently owing to a disordered state of the *primæ viæ*, often met with in persons who live on acrid irritating food, and drink too much spirits.—(*Scarpa, Sulle Malattie degli Occhi, cap.* 2. See also *Guthrie's Operative Surgery of the Eye, p.* 107, *&c.*)

HOSPITAL GANGRENE.—(*Phagedæna Gangræ-nosa; Putrid or Malignant Ulcer; Hospital Sore; Gangræna Contagiosa.*) A severe and peculiar species of humid gangrene, or rather a combination of this affection with phagedenic ulceration. It is particularly characterized by its contagious or infectious nature; its disposition to attack wounds, or ulcers, in crowded hospitals, or other situations, where many of these cases are brought together; and its tendency to convert the soft parts affected into a putrid glutinous, or pulpy substance, in which no trace of their original texture is discernible.—(*Delpech, Précis Elém. des Mal. Chir. t.* 1, *p.* 123.) It is generally believed to be communicated from one sore or wound to another, by its contagious nature; but, whether the infection can be transferred only by actual contact, or both in this way and through the medium of the atmosphere, is a question on which the best authors differ. The first origin of the disease, however, is a mysterious subject, which cannot invariably be explained on any certain principles, as will be hereafter noticed.

From the researches of Mr. Blackadder, it appears probable that several of the ancient writers, in their descriptions of foul gangrenous bleeding ulcers, must have alluded to the same kind of disease which is now usually denominated hospital gangrene. Besides the use of the actual cautery, which, according to the modern French writers, is the surest means of arresting this distemper, several of the ancients appear also to have employed for its cure arsenical applications; as, for instance, Ætius, Paulus, Rolandus, Avicenna, Guido, &c. The only doubt whether these authors actually referred to hospital gangrene depends upon their not having generally described its contagious nature. But on this point, I recommend Mr. Blackadder's valuable treatise to be consulted.—(*P.* 76, &c.)

Although La Motte made cursory mention of hospital gangrene in 1722, under the name of *pourriture*, and stated that it had occurred in the Hôtel-Dieu at Paris, the first distinct modern account of this disease is contained in the 3d vol. of the posthumous works of Pouteau, published in 1783. In the year 1788, Dussassoy, who succeeded Pouteau as chief surgeon of the Hôtel-Dieu at Lyons, also published a short treatise on the disorder. The first very accurate description of hospital gangrene in the English language appeared in the 6th vol. of the *London Medical Journal*, printed in 1785. The account is entitled, "Observations on the Putrid Ulcer, by Mr. Gillespie, surgeon of the Royal Navy." In the edition of Dr. Rollo's works on Diabetes, published 1797, there is a section on this subject, entitled, "A short account of a morbid poison, acting on sores, and of the method of destroying it." In 1799 Sir Gilbert Blane, in the third edition of his book on the Diseases of Seamen, gave an account of hospital gangrene under the name of malignant ulcer; and Dr. Trotter, in the 2d volume of his *Medicina Nautica*, published in the same year, described that affection by the same appellation. In the third volume of the same work, Dr. Trotter added to his first account several valuable communications relating to this disease, received from surgeons of the royal navy. Mr. John Bell also made hospital gangrene the subject of particular remark in the first volume of his *Principles of Surgery*, published in 1801. According to Dr. Thomson, two excellent theses were likewise published on it in the university of Edinburgh: the first, entitled, "De Gangrenâ Contagiosâ," by Dr. Leslie, in 1804; the second by Dr. Charles Johnson, in 1805, under the title of "De Gangrenâ Contagiosâ Nosocomiale."—(See *Lectures on Inflammation, p.* 456—458.)

Professor Thomson's account of the subject, published in 1813, contained the fullest history of the disease at that time collected. Boyer afterward gave a very fair account of the distemper.—(See *Traité des Mal. Chir. t.* 1, *p.* 320, 8*vo. Paris*, 1814.)

These descriptions were followed by the valuable essay of Delpech, entitled, "Mémoire sur la Complication des Plaies et des Ulcères connue sous le nom de Pourriture d'Hôpital," 1815; some interesting observations by Dr. Hennen, in the *London Medical Repository for March*, 1815; a paper by Professor Brugmann, of Leyden, in the "Annales de Littérature Méd." vol. 19, 1815; and the treatise of Mr. Blackadder, which contains some of the best remarks ever made concerning this affection, and is entitled "Observations on Phagedæna Gangrænosa, 8vo. Edinb. 1818." To these publications are to be added the interesting remarks of Mr. R. Welbank on Sloughing Phagedæna, contained in the eleventh volume of the *Med. Chir. Trans.*; and those of Dr. Boggie, recorded in the third volume of the *Edin. Med. Chir. Trans.*

According to Mr. Blackadder, who is a believer in the doctrine of the complaint being only communicable by the direct application of the infectious matter, when the morbific matter which produces the disease, has been applied to some part of the surface of the body, from which the cuticle has been removed, as by a blister, one or more small vesicles first appear, which are filled with a watery fluid, or bloody serum of a livid or reddish-brown colour. The situation of the vesicle is generally at the edge of the sore. Its size is not unfrequently that of a split garden pea, and is easily ruptured, the pellicle which covers it being very thin. When the vesicle is filled with a watery fluid, and has not been ruptured, it assumes the appearance of a grayish-white, or ash-coloured slough; but when it contains a dark-coloured fluid, or has been ruptured, it puts on the appearance of a thin congulum of blood, of a dirty brownish-black colour. During the formation of the vesicle, there is generally a change in the sensation of the sore, accompanied with a painful feel like that of the sting of a gnat.

After a slough is formed, it spreads with more or less rapidity, until it occupies the whole surface of the original sore; and when left to itself (which seldom happens), there is little or no discharge, but the slough acquires daily greater thickness.

"When the formation of the slough has been interrupted, the stinging sensation becomes more frequent and acute; phagedenic ulceration quickly commences; and such is frequently the rapidity of its progress, that even in the course of a few hours, a very considerable excavation will be formed, while the parts in the vicinity retain their usual healthy appearance." The cavity, the edges of which are well defined, is filled with a thick glutinous matter, which adheres strongly to the subjacent parts. When this matter is removed, the surface underneath presents itself of a fine granular texture, which, in almost all instances, is possessed of extreme sensibility, and is very apt to bleed when the operation of cleaning is not performed with great delicacy. At each dressing, the circumference of the cavity is found enlarged, and if there are more than one, they generally run into each other. The progress of the disease is much quicker in some individuals than others, but *it never ceases until the whole surface of the original sore is occupied*. The stinging pain gradually becomes of a darting or lancinating kind; and *either about the fourth or sixth day from the time when the morbific matter had access to the sore, or afterward, at the period of what may be termed secondary inflammation, the lymphatic vessels and glands are apt to become affected*. The discharge becomes more copious, its colour varying from a dirty yellowish-white, to a mixture of yellow, black, and brown, depending upon the quantity of blood mixed with it.

"The soft parts in the immediate vicinity of the sore, daily become more painful, tumefied, and indurated; and in a great number of cases, particularly in those of plethoric and irritable habits, an attack of acute inflammation speedily supervenes, and is accompanied by a great increase of pain, the sensation being described to be such as if the sore were burning. The period at which this inflammation begins to subside is by no means regular. Sometimes it subsides in the course of two days, and sometimes it continues upwards of five; depending very much on the constitution and previous habits of the patient, as well as the treatment that has been adopted. During its progress, the thick, putrid-looking, and frequently spongy slough which is formed on the sore, becomes more and more moist, and of a *pulpy* consistence. (Hence this form of disease is actually named by Gerson, *pulpa gangrene*.) In the course of a few days, a very offensive

matter begins to be discharged at its edges. The slough then begins to separate; by-and-by it is thrown off, but only to prepare the way for an extension of the disease by a continued process of ulceration, and by a recurrence of the last mentioned symptoms."—(*Blackadder on Phagedæna Gangrænosa, p.* 28—30.)

The first symptoms which indicate hospital gangrene in a wound or ulcer, are, a more or less acute pain, and a viscid whitish exudation on the surface of the granulations, which lose their vermilion colour, and present at several points, spots of a grayish or dirty-white hue, resembling venereal ulcers or aphthæ. These ulcerated points, thus engrafted (as it were) upon the original ulcer, soon spread and join together, so as to give to the whole surface of the solution of continuity a gray ash colour. The surface also becomes more or less indurated, and sometimes bleeds. A red purplish œdematous circle, of a greater or less extent, is next formed in the surrounding skin. Sometimes when the patient is of a good habit, the causes of infection less active, and the constitution sufficiently strong, the disorder now stops. According to Boyer, it may not even extend to the whole surface of the ulcer. But most frequently its progress is extremely rapid, and occasionally quite terrifying. The edges of the wound or ulcer become hardened and everted; the granulations are large and tumid, being swelled up, as Boyer asserts, with a considerable quantity of gas. They are afterward detached in the form of soft reddish sloughs, which very much resemble the substance of the fœtal brain, in a putrid state. From day to day, until either nature alone, or aided by art, puts limits to the disorder, it invades new parts both in breadth and depth, so that its ravages extend to aponeuroses, muscles, blood-vessels, nerves, tendons, the periosteum, and even the bones themselves.

Among a number of severe cases which fell under the notice of Mr. Blackadder, "there was one in which the half of the cranium was denuded, the bones having become black as charcoal, and the integuments detached posteriorly to the second cervical vertebra, and anteriorly to the middle of the zygomatic process of the temporal bone; and this was originally a superficial wound of the scalp. In another case, the muscles, large arteries, and nerves of both thighs were exposed and dissected, the integuments and cellular substance being entirely removed, with the exception of only a narrow strip of the former, which remained on the outer side of the thighs. This was also originally a simple flesh wound. In other instances, the cavities of the knee, ankle, elbow, and wrist joints were laid extensively open, and, in one unfortunate case, the integuments and cellular substance on the anterior parts of the neck, were destroyed, exhibiting a horrid spectacle, the trachea being also wounded."—(*On Phagedæna Gangrænosa, p.* 3.)

According to the last experienced author, when the disease attacks an old sore, where a considerable depth of new flesh has been formed, the first thing generally observed is a small dark-coloured spot, usually situated at the edge of the sore. But he states, that in several cases of ulcers, the disease, when carefully watched, was found to begin in the form of a vesicle, filled with a livid or brownish-black fluid, which afterward burst and assumed the appearance of the dark-coloured spot, which is commonly first noticed. Mr. Blackadder always found, that when there had been a considerable bed of new flesh formed, the phagedenic ulceration made comparatively a very slow progress, and put on rather the appearance of mercurial phagedena, until the morbific matter had found access to the natural texture of the part, when the progress of the disease became suddenly accelerated; acute inflammation supervened; and a large slough was formed.—(*Op. cit. p.* 31.) He notices, that when the morbific matter is inserted in a puncture or scratch, the first progress of the disease bears a resemblance to that of a part inoculated with vaccine matter. The primary inflammation in gangrenous phagedena commences at the end of the second, or early on the third day; the inflammation is at its height about the sixth; when the scab begins to form in one disease, phagedenic ulceration begins in the other, and when allowed to proceed, soon affords sufficient proof of the non-identity of the two diseases.—(*P.* 33.)

When the disease attacks a recent gunshot wound, the discharge, two or three days after infection, is found to be lessened, and to have become more of a sanious than purulent nature. The sore has a certain dry and rigid appearance; its edges are more defined, somewhat elevated and sharpened; the patient is sensible of a change in the usual sensation in the sore, and complains of an occasional stinging sensation, resembling that produced by the sting of a gnat. At this period, but sometimes a day or two later, the integuments at the edge of the sore become inflamed, and the surface of the sore itself assumes a livid or purple colour, and appears as if covered with a fine pellicle, such as is formed on a coagulum of blood.—(*On Phagedæna Gangrænosa, p.* 33.)

At Bilboa, the disease, in cases of wound, is said generally to have commenced with a sudden attack of severe pain in the head and eyes, tightness about the forehead, want of sleep, loss of appetite, a quick pulse, and other febrile symptoms; while the wound, which had been healthy and granulating, at once became tumid, dry, and painful, losing its florid colour, and assuming a dry and glossy coat.—(*Hennen on Military Surgery, p.* 214, *ed.* 2.) When left to itself, the above-described pellicle gradually increases in thickness, forming what has been termed a slough. But Mr. Blackadder observes, that at this period the progress of the disease is hardly in any two instances precisely alike. Generally, in the course of from five to ten or fifteen days, a thick spongy and putrid-looking slough is formed over the whole surface of the sore, and which is more or less of an ash, or blackish-brown colour. When the pellicle is destroyed, as frequently happens in the process of cleaning, it is not in every case reproduced; but an offensive matter begins to be discharged, which becomes daily more copious, is of a dirty yellow colour and ropy consistence, and is very adherent to the sore. The substance which formed the apparent bottom of the wound is raised up, and pushing back the edges, makes the sore appear considerably enlarged. The edges, which are usually jagged or pectinated, become extremely irritable, of a deep-red colour, and dotted on their inner surface, with numerous small, elevated, and angry-looking points, *which may be considered as one of the characteristic marks of the disease.* The surrounding integuments become indurated and inflamed, assuming, not unfrequently, an ansarine appearance; and the patient complains of a constant burning lancinating pain. In the vicinity of the sore, the integuments become more and more of a dark-red colour, in consequence of the violence of the inflammation, which is of an erysipelatous nature, and apt to terminate in sloughing, and carry off the patient. However, the inflammatory symptoms are sometimes mild, and in other cases, exceedingly violent; a fact accounted for by differences of constitution.—(*Blackadder, p.* 34.)

In the hospitals at Bilboa, if the incipient stage was overlooked, the febrile symptoms very soon became aggravated; the skin around the sore assumed a highly florid colour, which shortly became darker, then bluish, and at last black, with a disposition to vesicate; while the rest of the limb betrayed a tendency to œdema. All these threatening appearances occurred within twenty-four hours, and at this period also, the wound, *whatever might have been its original shape, soon assumed the circular form.* The sore now acquired hard, prominent, ragged edges, giving it a cup-like appearance, with particular points of the lip of a dirty yellow hue, while the bottom of the cavity was lined with a flabby blackish slough. The gangrene still advancing, fresh sloughs were rapidly formed; the increasing cup-like cavity was filled up and overtopped by them, and the erysipelatous livor and vesication of the surrounding skin gained ground, while chains of inflamed lymphatics could be traced from the sores to the adjoining glands, these exciting inflammation and suppuration, which often furnished a new nidus for gangrene. The face of the sufferer assumed a ghastly anxious appearance: his eyes became haggard and deeply tinged with bile; his tongue covered with a brownish or blackish fur; his appetite entirely failed; and his pulse was feeble and accelerated. In this stage, the weakness and irritability of the patient was such, that the slightest change of posture put him to torture, increased by his inability to steady the limb, which, if lifted from the bed, was seized with tremors and spasmodic twitches.—(*Hennen's Military Surgery, p.* 215, 216, *ed.* 2.) Authors vary consider

ably in their descriptions of the state of the tongue. Dr. Hennen found it brownish or blackish; Delpech, whitish or yellowish (*Précis Elém. t.* 1, *p.* 125.); and Mr. Blackadder, covered with a white mucus.—(*P.* 39.)

It is explained by Mr. Blackadder, that when the disease attacks a large recent wound, the whole surface of the injury is sometimes affected from the first; while in other instances, the disorder commences on or near the lips of the sore. When the patient is of an inflammatory diathesis, the sore is generally attacked with acute inflammation between the seventh and fourteenth days; and the slough is softer and of a pulpy consistence; matter of a strong and peculiar odour, and of a dirty brownish gray colour, begins to ooze out at its edges, and becomes daily more copious. The inflammation gradually subsides; the slough becomes loosened and finally detached, leaving the subjacent muscles, bones, fasciæ, or ligaments, completely exposed When the constitution is not prone to acute inflammation, the slough remains long adherent; the discharge is very copious, and burrows under the skin, which then mortifies. Sometimes, after the detachment of a slough, florid granulations spring up, and notwithstanding a slight recurrence of the phagedenic ulceration, the parts heal up by the almost unassisted operations of nature. However, most commonly after the muscles are exposed, they continue to be gradually dissected; their connecting cellular membrane is completely destroyed, and they are left covered with an offensive greasy looking matter.

According to Mr. Blackadder, when a muscle has been wounded, it swells sometimes to a great size, and quickly assumes the appearance of a large coagulum, being altogether deprived of irritability. When it has not been wounded, but has become inflamed, it generally assumes a pale colour, with an appearance as if distended with a fluid, and occasionally before losing its vitality, acquires a very surprising bulk; but when no inflammation has supervened, the muscles become of a pale brick colour, waste away daily, and the patient loses all power in them. As the disease advances, the integuments are undermined, and slough; and hemorrhage from small vessels is a common occurrence; but in a more advanced stage, some of the large vessels are apt to give way, and the bleeding from them frequently destroys the patient.

"When a stump is the site of the disease, and the patient is of a plethoric habit, or accustomed to live freely, the symptoms soon begin to indicate the existence of an intense inflammatory action through its whole substance, the tumefaction, pain, and heat increase rapidly, so that in a few days, the stump shall have acquired more than twice its former size, being at the same time much indurated, and causing the most excruciating pain In this state, the patient has, in some instances, become delirious, and has been cut off by an effusion taking place into some of the larger cavities. It more commonly happens, however, that gangrene seizes upon the integuments and cellular substance; large sloughs are thrown off; and some of the large blood-vessels giving way, the patient sinks under the effects of repeated hemorrhage. For it is commonly found, that the usual modes of stopping hemorrhage from a stump, are, in such cases, either inadmissible or totally inefficacious.

"Sometimes the progress of the disease in a stump is more gradual, but in the end nearly as fatal; the inflammation is much less acute; there is comparatively but little tumefaction, and the pain is much less severe; but the discharge is much more copious, and the cellular substance connecting the integuments and muscles is rapidly destroyed. Hemorrhage generally comes on later than in the preceding instance, but it is the most common cause of death."—(*Blackadder on Phagedæna Gangrænosa, p* 33—39.)

It is observed by another writer, that artery seems to be the texture which resists most powerfully the destructive action of hospital gangrene (*Thomson's Lectures, p.* 460): a remark quite at variance with the statement of Delpech (*Précis Elém. t.* 1, *p.* 129); but intended to refer, as I conceive, to cases in which the femoral, brachial, or other large artery is seen for several days completely denuded in the midst of the ravages of the distemper, yet not giving way. I have seen the same thing frequently exemplified in mercurial phagedena, as well in the groin as in the arm. As for the smaller arteries, they are quickly destroyed, together with other parts.

"In some rare cases (says Dr. Hennen,) I have seen the femoral and axillary arteries pulsating awfully, and apparently unaffected with disease; while all the surrounding parts were completely destroyed: but in a vast majority of cases the blood-vessels partook of the general disease in which they were imbedded. They were not only completely separated from their natural connexions, but their coats sloughed away at the immediate point of disease, while the disposition extended far beyond the apparently affected spot. Hence, our ligatures but too often failed on the main branches, and any attempt on the smaller was invariably injurious. We were here naturally induced to tie the artery considerably above the seat of the disease; and this was done once on the femoral, and twice on the axillary artery below the clavicle: the former burst on the third, each of the latter on the second day afterward." Dr. Hennen further remarks, that, in general, the great vessels sloughed long after the new acute symptoms of the disease had abated, and that, in severe cases, the eleventh day of the disease was always dreaded.—(*On Military Surgery, p.* 221, *ed.* 2.) The indisposition of the large vessels to close, when taken up in the common way, appears referable to three causes: viz. the tendency to rapid ulceration in the arteries in the situation of the ligatures; the formation of no effectual coagulum in the extremity of the vessel, like what happens in other cases of mortification; and the general incapacity of nature in examples of hospital gangrene to establish any process which can be accompanied with healthy adhesive inflammation.

In the last stage of the disease, as it occurred in the military hospitals at Bilboa, the surface of the sore was constantly covered with a bloody oozing, and on lifting up the edge of the flabby slough, the probe was tinged with dark-coloured grumous blood, with which also its track became immediately filled. Repeated and copious venous bleedings now came on, which rapidly carried off the patient: the sloughs, whether they fell off spontaneously, or were detached by art, were quickly succeeded by others, and brought into view thickly studded specks of arterial blood. At length, an artery gave way, which was generally torn through in the attempt to secure it with a ligature: the tourniquet, or other pressure, was now applied, but in vain; for while it checked the bleeding, it accelerated the death of the limb, which became frightfully swelled and horribly fetid. Incessant retchings came on, and with coma, involuntary stools, and hiccough, closed the scene Often, however, the patient survived this acute state of the disease, and sank under severe irritation, absorption of putrid matter, and extensive loss of substance, with common hectic symptoms.—(See *Hennen's Mil. Surgery, p.* 217, *ed.* 2.) In the disease at Bilboa, the skin and cellular substance seemed to be the parts originally and principally affected. This, says Dr. Hennen, was obvious, even in the living body; but on dissection the disease of these parts was frequently observed to spread much further than external appearances indicated, as a diseased track was often found running up into the groin, or axilla, and completely dissecting the muscles and great vessels.—(*On Military Surgery, p.* 219, *ed.* 2.) When the disease had occupied the outside of the chest, the same gentleman found the lungs in two cases, and the pericardium in a third, covered with gangrenous spots; and when the parietes of the abdomen had been attacked, he often observed the same appearances on the liver.—(*P.* 220.)

Hospital gangrene must be regarded as one of the most serious and dangerous complications to which wounds and ulcers are liable. When the solution of continuity is large, or of long standing, the disorder commits great ravages, renews its attacks repeatedly, and the relapses prove exceedingly obstinate. The same thing is said to happen when it affects persons labouring under scorbutic or venereal complaints. Hospital gangrene proves particularly dangerous, and mostly fatal, when it complicates large contused wounds, attended with badly fractured bones. All the soft parts of the injured limb are then frequently observed to be progressively destroyed, and the unfortunate patient falls a victim either to typhoid symptoms, frequent hemorrhages, or hectic complaints. From what has been stated, however, the disease varies

considerably in its severity in different cases, being sometimes of small extent, and even capable almost of a spontaneous cure. Patients have been known to continue afflicted more than a month; and when the duration of the disease was thus lengthened, the cases almost always had a fatal termination. In a few cases, the wound puts on a favourable appearance again between the sixth and ninth days; and, in slight examples, the amendment is manifested between the third and fifth. Whatever may be the period of the complaint, its wished-for termination is always announced by a diminution of pain; the pus acquiring a white colour, and more consistence, and losing its fetid nauseous smell. The edges of the ulcer subside, while its surface becomes less irregular, and puts on more of the vermilion colour. The red, purplish, œdematous circle, which surrounds the disease, assumes a true inflammatory nature; and the solution of continuity, restored to a simple state, heals up with tolerable quickness, even when the destruction of soft parts is somewhat considerable, unless any fresh untoward circumstances occur to interrupt cicatrization. But sometimes when the patient is on the point of being completely well again, his condition is suddenly altered for the worse; ulcerated spots make their appearance on the cicatrix, and these spreading in different directions occasion a relapse, which may happen several times.

According to Dr. Boggie, a relapse, and even repeated relapses, are very common, as his own experience fully convinced him; and he adverts to a case reported by Dr. Hennen, in which the patient survived twelve different attacks, and sunk under the thirteenth. —(See *Edinb. Med. Chir. Trans. vol.* 3, *p.* 8.) As far as the observations of Dr. Boggie went, hospital gangrene is more frequent and severe in hot weather than cold.—(See *Edinb. Med. Chir. Trans. vol.* 3, *p.* 13.)

From numerous cases of this disease, seen by Mr. Blackadder at Passage in Spain, this gentleman made the following conclusions:

1. That the morbid action could almost always be detected in the wound, or sore, *previously to the occurrence of any constitutional affection.*

2. That in several instances the constitution did not become affected until some considerable time after the disease had manifested itself in the sore.

3. That when the disease was situated on the inferior extremities, the lymphatic vessels and glands in the groin were observed to be in a state of irritation, giving pain on pressure, and were sometimes enlarged, before the constitution showed evident marks of derangement.

4. That the constitutional affection, though sometimes irregular, was in many cases contemporary with the second or inflammatory stage.

5. That all parts of the body were equally liable to become affected with this disease.

6. That when a patient had more than one wound, or sore, it frequently happened that the disease was confined to one of the sores, while the other remained perfectly healthy, and this even when they were at no great distance from each other.—(*On Phagedæna Gangrænosa, p.* 19.)

Thus Mr. Blackadder espouses the opinion that hospital gangrene is at first *local*, and not a *constitutional disease*; that is to say, not necessarily preceded, or originally accompanied by, any diseased action in the system. It is highly important to weigh this distinction well; not only because it is yet the chief point of difference among the best writers on the subject, but because it involves very directly every theory respecting the causes of the disease and the great question, whether its ravages are to be resisted principally by local or constitutional means, or by remedies of both descriptions together.

In the hospital gangrene, observed by Dr. Rollo in the Artillery Hospital at Woolwich, "the action of the poison seemed to be limited and confined to specific effects. *The first were local, producing only a general affection by a more extensive operation on the sore.* Five or six days from the appearance of the small ulcer or ulceration, when it had extended over one-third of the former sore, with pain and redness in the course of the lymphatics and the glands through which they led, with enlargement of them, general indisposition of the body became evident." Delpech, in his interesting memoir, particularly notices, that the constitutional symptoms *always occurred the last in order of succession.*

Mr. Blackadder distinctly declares, that in no instance which he had had an opportunity of observing, did the constitutional symptoms of gangrenous phagedena precede the local, unless the case be held an exception, in which a stump became affected after amputation had been performed, on account of the previous effects of the disease. The period at which the constitution begins to exhibit symptoms of irritation (he says) is extremely irregular,—sometimes as early as the third or fourth day, and sometimes even as late as the twentieth. The countenance assumes an anxious or feverish aspect; the appetite is impaired; the desire for liquids increases; and the tongue is covered with a white mucus. The bowels are generally rather constipated; and the pulse what may be termed rather irritated than accelerated. But the general symptoms may assume an inflammatory, or typhoid character, according as the causes of one of these modifications may predominate. According to Mr. Blackadder, when an inflammatory diathesis prevails, the system becomes gradually more irritated, until an attack of acute inflammation seizes upon the sore, and which frequently happens about the end of the second week. At this period the pulse is frequent and sharp, and it is not uncommon for the patient to be seized with one or more shivering fits, succeeded by a great increase of heat, but seldom or never terminating in a profuse perspiration. The cold fit is sometimes followed by a bilious discharge from the intestines and nitigation of the febrile disorder. If the local mischief be not arrested, the strength becomes daily more and more exhausted; the fever loses its inflammatory character; and unless the patient be cut off by hemorrhage, he falls a victim to extreme debility. When the disease has a typhoid character, the pulse is small and frequent; the appetite and strength gradually fail; and the patient at last sinks, retaining his mental faculties to the last. No. unfrequently diarrhœa hastens the event.—(*Blackadder on Phagedæna Gangrænosa, p.* 39, 40.)

The sloughing phagedena seen by Mr. R. Welbank, generally in the cleft of the nates, in the groin, or at the inner and upper part of the thigh, in the lowest class of prostitutes, and, according to his description, certainly resembling hospital gangrene, was attended in its early stages with little or no disturbance of the system: a circumstance which he also mentions as favourable to the doctrine that the disease is of a local nature.—(See *Med. Chir. Trans. vol.* 11, *p.* 365.)

On the other hand, the generality of writers, nay, even some of those who represent the disease as always proceeding from a species of infection applied to the wound, take into the account the operation of constitutional causes, as predisposing to, and of course preceding, the local symptoms. Dr. J. Thomson believes that the constitutional symptoms mostly precede the local.—(*On Inflammation, p.* 459.) The same sentiment is professed throughout Dr. Hennen's remarks, who placed reliance chiefly upon internal remedies, and regarded external applications as merely a secondary object.—(*On Military Surgery, p.* 222, *ed.* 2.) To this part of the subject I shall return, after adverting to the causes of hospital gangrene.

The hospital gangrene which occured in the Artillery Hospital at Woolwich, and was described by Dr. Rollo, did not attack specific sores: venereal, scrofulous, and variolous ulcers were not attacked, although the patients lay in the wards where the disease prevailed.

Professor Thomson admits that specific sores are less liable to attacks of hospital gangrene than common wounds and ulcers; but he declares, that he has frequently seen it attack cancerous and venereal ulcers.—(*On Inflammation, p.* 460.)

Dr. Hennen mentions a remarkable instance, which also proves the possibility of a specific sore becoming affected, and fatal from this cause in forty-eight hours after the patient had first been exposed to the infection. Dr. Hennen relates the fact to prove, that the contagion may be received without a long residence in a tainted air. The patient, "who had just landed from England, and was under the influence of mercury, employed for a venereal complaint, died within forty-eight hours after his admission; the gangrene having seized on an open bubo in his groin, eroding the great vessels in the

neighbourhood, and absolutely destroying the abdominal parietes to a large extent."—(*Principles of Military Surgery, p.* 218, *ed.* 2.)

The effects of hospital gangrene should be carefully discriminated from those of the scurvy. Ulcers attacked with hospital gangrene are not affected in any degree, like scorbutic ulcers, by the use of vegetable diet and lemon juice; and they occur among men who are fed upon fresh meat and vegetables, as readily as they do among those who have been fed altogether upon salt provisions.—(*Thomson's Lectures on Inflammation, p.* 482.) Hospital gangrene is almost always accompanied with severe febrile symptoms; but "as to fevers (says Dr. Lind), it may indeed be doubted whether there be any such as are purely and truly scorbutic. The disease is altogether of a chronic nature; and fevers may be justly reckoned among its adventitious symptoms."—(*Treatise on the Scurvy, p.* 106.) In cases of hospital gangrene, the general symptoms of scurvy are also absent, such as soreness and bleeding of the gums, livid blotches and wheals on the fleshy part of the legs, œdematous ankles, &c.

Hospital gangrene (says Boyer) is a species of humid gangrene, which attacks in some degree *epidemically* the wounds and ulcers of patients who happen to be crowded together in an unhealthy place.

Its occasional causes are: the situation of an hospital upon a low marshy ground; the vicinity of some source of infection; the uncleanliness of the individuals, or of the articles for their use; the crowded state of the wards, especially when they are small and badly ventilated; lastly, every thing that tends to corrupt the air which the patients breathe. An infected atmosphere may produce in the most simple wounds unfavourable changes, partly, as Boyer conceives, by its immediate action on the surface of the wound, but, no doubt, principally, by its hurtful influence upon the whole animal economy. The foregoing causes have also sometimes produced alarming and obstinate gangrenes of an epidemic kind, or, at least, a state of the constitution, under the influence of which all wounds and ulcers constantly took on a bad aspect, and were often complicated with the worst gangrenous mischief. Vigaroux saw such an epidemic disease prevail for twenty months in the two hospitals of Montpellier, and he states that the most powerful antiseptics were of little avail against the disorder, which often invaded the slightest scratches.

In general, this epidemic species of gangrene is not observed in new-built hospitals, nor in those which are erected out of the central parts of cities upon high ground. Hospital gangrene may occur in any season; but it is most common after the sultry heat of summer.

A bilious constitution, mental trouble, unwholesome or insufficient food, a scorbutic diathesis, great debility, and fevers of a dangerous type, are also reckoned by the French surgeons as so many predisposing causes of hospital gangrene.

The observations of Pouteau, and those of some other practitioners, convincingly prove that hospital gangrene may be communicated to the most simple wound or ulcer in a subject of the best constitution, and breathing the purest air, by merely putting into contact with such wound or ulcer, sponges, lint, or charpie, impregnated with the infection of this peculiar disorder. But this inoculation is conceived to be the more alarming, and to take effect the more quickly, in proportion as patients have been more exposed to the influence of such causes as are themselves capable of producing the disease, and also in proportion as the kind of constitution predisposes to it.

Although the contagious nature of hospital gangrene has been generally admitted by all the best-informed writers on the subject, the doctrine was not considered by Dr. Trotter as having a good foundation. Modern authors, however, have not joined this latter gentleman, and Dr. J. Thomson, Dr. Hennen, Mr. Blackadder, and Mr. R. Welbank, all believe that the disorder is infectious. "The contagious nature of hospital gangrene (says Professor Thomson) appears to me to be sufficiently proved, 1st, By the fact, that it may be communicated by sponges, charpie, bandages, and clothing, to persons at a distance from those infected with it. 2dly, By its having been observed to attack the slight wounds of surgeons, or their mates, who were employed in dressing infected persons; and that even in circumstances where the medical men so employed did not live in the same apartment with the infected. 3dly, By our being able often to trace its progress distinctly from a single individual through a succession of patients. 4thly, By its attacking recent wounds, as well as old sores, and that in a short time after they are brought near to a patient affected with the disease. 5thly, By our being able to prevent the progress of the disease in particular situations, by removing the infected person before the contagion, which his sores emit, has had time to operate. 6thly, By its continuing long in one particular ward of an hospital, or in one particular ship, without appearing in other wards, or ships, if pains be taken to prevent intercourse between the infected and uninfected."—(*Lectures on Inflammation, p.* 484.) But although there can be no doubt of the disease spreading partly by its contagious nature, it appears to me equally certain that the number of cases is also often increased by the continued operation of the same causes which produced the earliest instance of the disorder in any particular hospital. A similar belief is expressed by Dr. Boggie.—(See *Edinb. Med. Chir. Trans. vol.* 3, *p.* 25.)

It is alleged, that when once a patient has taken the infection, he cannot avoid the consequences, whatever precautions he may adopt. Thus, Boyer informs us, that he has seen hospital gangrene take place in wounded patients, who, in the hope of escaping this epidemic affection, had quitted the infected hospital, and retired to elevated situations, where they breathed the most salubrious air.—(See *Traité des Mal. Chir. t.* 1, *p.* 322.)

The bad state of the air of a crowded hospital, as Mr. Blackadder observes, is a ready means of accounting for the origin of phagedæna gangrænosa; but there are various reasons for considering such explanation not altogether satisfactory; and he mentions a case, in which the wound of a soldier was found affected with the disease on his first arrival at an hospital, after having been accidentally detained, with two other wounded comrades, for five or six days, partly in an open building, and partly in a boat, quite exposed to stormy weather.—(*P.* 45.) Dr. Hennen likewise gives an account of about thirty fresh wounded men, in whom hospital gangrene first appeared in their journey from Vittoria to the hospital near Bilboa.—(*Principles of Military Surgery, p.* 214, *ed.* 2.) Dr. Rollo also remarked, that some men in quarters were affected with this disease. And, according to Mr. J. Bell, "there is no hospital, however small, airy, or well regulated, where this *epidemic* ulcer is not to be found at times."—(*Principles of Surgery, vol.* 1, *p.* 112.) For a refutation of the opinion, that the disease strictly merits the epithets *endemial* and *epidemic*, I must refer the reader to the observations of Mr. Blackadder.—(*P.* 143, *&c.*) Delpech remarks, that the causes of the disease do not appear to have depended upon the state of the atmosphere (*p.* 25); and, in almost every instance, *he traced the propagation of the disorder to the direct application of the morbific matter to the sores.* However, he joins Pouteau in the belief, that it may be communicated through the medium of the atmosphere; an occurrence which Mr. Blackadder doubts, or rather considers as very rare, and only possible where the effluvia are allowed to accumulate in a most negligent manner, so as to resemble a vapour bath, which mode he would also regard as equivalent to inoculation.—(*On Phagedæna Gangrænosa, p.* 156.) On the whole, I am disposed to think the views which Mr Blackadder has taken of the manner in which the disease is communicated the most correct, and that, while particular states of the air and constitution certainly modify the disorder, they cannot generally have any share in giving origin to the disease: I say *generally*, because, as various facts oblige us to admit, that hospital gangrene sometimes arises without having been communicated from any patient previously affected, it is impossible to assert, that the earliest example of it, under such circumstances, may not arise from the operation of some unknown and inexplicable circumstances on the constitution, or, in other words, from the state of the system itself. Nor can a doubt be entertained, that at all events, the disorder is most apt to break out in crowded, badly ventilated hospitals, and in them appear more extensively and malignantly than in others which are well regulated, properly ventilated, and healthily situated. But the idea entertained by Delpech, that hospital gangrene may originate from the

same contagion as typhus, or other diseases, is merely an unsupported, irrational conjecture, quite as destitute of truth as the suppositions about the endemial and epidemic character of the complaint, independent of its infectious nature. The question, how the first example of the disorder originates, is at present a perfect mystery; but, as it cannot be referred to contagion, or inoculation, we should recollect, that whatever produces it in one individual may produce it in another, similarly circumstanced, and, on this principle, the disorder may sometimes be formed independently, and at the same time, in a greater or less number of patients in the same hospital, as well as spread from these to others by infection.

With the view of preventing the disorder, the wards in which the wounded are placed should not be crowded: they ought to be freely ventilated, and if possible not communicate. The utmost attention to cleanliness should be paid, and all filth and stagnant water removed. It has been asserted, but with what accuracy I cannot determine, that the predisposition of the wounded to this species of gangrene may be lessened by a well chosen diet, by drinks acidulated with vegetable acids, or with the sulphuric acid, and by the moderate use of wine. The state of the stomach and bowels should be particularly attended to, and if out of order emetics and purgatives ought to be immediately employed, and repeated according to circumstances. The dressings should be applied with extreme attention to cleanliness, and too much care cannot be taken to prevent the infectious matter of one wound from coming into contact with another, through the medium of sponges (see *Welbank, in Med. Chir. Trans. vol.* 11, *p.* 365), instruments, &c. "Whatever may be the source of this disease (says a late writer), it is at least sufficiently ascertained, that when it occurs, its propagation is only to be prevented by the most rigid attention to cleanliness, and by insulating the person or persons affected, so as to prevent all direct intercourse between them and the other patients; for, so far as I have had an opportunity of observing, ninety-nine cases in the hundred were evidently produced by a direct application of the morbific matter to the wounds, dressings, &c.; while others, who were in every other respect equally exposed to its operation, never caught the disease. In attempting to prove this by experiment, I have placed three patients with clean wounds alternately between three other patients severely affected with the disease. They lay in a part of a ward which was appropriated for patients who were labouring under the disease, and of whom there were at the time a considerable number. Their beds were on the floor, and not more than two feet distant from each other; but all direct intercourse was forbidden, and they were made fully aware of the consequences that would follow from inattention to their instructions. The result of this trial was, that not one of the clean wounds assumed the morbid action peculiar to the disease, nor was the curative process in any degree impeded."—(*Blackadder on Phagædena Gangrænosa, p.* 46)

As many experienced writers assert, that the disease may also be communicated from one person to another through the medium of effluvia in the air, I am firmly persuaded that, in the present state of our knowledge of the subject, the cautions respecting ventilation and cleanliness (the chief practical deduction from the latter doctrine) are highly necessary and important. This sentiment may be adopted, without implicit faith being placed in the opinion, that the disorder can actually be transmitted from one person to another through contagion in the air, because, whether the last idea be true or not, attention to cleanliness and ventilation must be beneficial to the health, in this, as in every other species of gangrene; and, on this principle, it must be serviceable in diminishing the severity, if not the frequency and extent, of the disease, as I am myself disposed to believe from the consideration of all the evidence adduced. These observations are strengthened by the fact, that it was chiefly in the foul wards of St. Bartholomew's Hospital, that the disorder committed its ravages in that institution.—(See *Med. Chir. Trans. vol.* 11, *p.* 365.) Where circumstances will permit, an entire removal of the patients from the place, in which the disease has either had its first formation, or spread to any extent, appears likewise to be a most beneficial measure. But when this change of the wards, or hospital, is impracticable, the air which the patients breathe should be purified, by renewing it as much as possible, fixing ventilators, and especially by using the oxygenated muriatic acid fumigations, as recommended by Guyton-Morveau, or else those of the nitric acid.

The nitric acid fumigations are made by putting into a glass vessel, on the ground, half an ounce of concentrated sulphuric acid, to which an equal quantity of nitre is to be added *gradatim*. The mixture is to be stirred with a glass tube, when an abundance of white vapour will be produced.

The oxygenated muriatic acid fumigations are made, by mixing three ounces two drachms of common salt with five drachms of the black oxyde of manganese in powder. These two ingredients are to be triturated together; they are then to be put into a glass vessel; one ounce two drachms of water are to be added, and then, if the ward or chamber be uninhabited, one ounce seven drachms of sulphuric acid are to be poured upon the mixture all at once; or, gradually, if the patients are there. This quantity will be sufficient for a very large ward.

When one or more of the patients afflicted with the disorder, before it has become general, are lying in a badly ventilated part of the ward, the surgeon can partly counterbalance the disadvantage of not having a fresh ward, by causing the patients to be put into a more airy part of the ward, and as far as possible from the quarter in which they contracted the disease.

With regard to internal medicines, while irritation and febrile heat accompany hospital gangrene, diluent acid drinks are proper, such as nitrated whey sweetened with syrup of violets, lemonade, &c. Bloodletting is admissible in but few instances; not merely because the orifice made by the lancet may, according to some accounts, become gangrenous, but because the fever, which accompanies hospital gangrene, is usually of the typhoid character.—(*Thomson, p.* 493.)

Mr Blackadder, like Dr. Thomson, does not entertain a favourable opinion of venesection, as a general practice, though he would not object to the abstraction of a small quantity of blood, when, owing to the plethoric habit of the patient, *previous treatment*, and other causes, an inflammatory action in the system is present. The same practice, under similar conditions, is also sanctioned by Dr. Boggie.—(*Edinb. Med. Chir. Trans. vol.* 3, *p.* 34.) Mr. Blackadder conceives, that all danger of the disease attacking the wound made with the lancet may be obviated, if care be taken, that the arm of the patient, the hands of the surgeon, his lancet, and the subsequent dressings, be perfectly free from contamination, and that the patient be prevented from undoing the bandage, or touching the incision made with the lancet before it is cicatrized.—(*P.* 135.) Dr. Boggie has bled many in this disease, but never seen a single instance of gangrene after the operation.—(*Edinb. Med. Chir. Trans. vol.* 3, *p.* 35.) Mr. Blackadder thinks, however, that blood-letting should be avoided as much as possible, particularly when the previous injury has been extensive. "A general debility of the system is one of the symptoms which are most to be dreaded; for, when once it takes place, there is no other disease in which it is removed with greater difficulty."—(*P.* 137.) How different these sentiments are from those of Dr. Hennen, who, in speaking of the effects of venesection, when the disorder was accompanied with an inflammatory diathesis, employs the following expressions: "The very patients themselves implored the use of the lancet." For several months "we used no other remedy, either as a cure or preventive."—"We never observed any of the lancet-wounds assume a gangrenous appearance, although previously, in almost every other instance, the slightest puncture festered."—(*On Military Surgery, p.* 224, *ed.* 2.) Mr. Welbank also states, that moderate venesection may be adopted with advantage while the disease is superficial, and the constitution not much affected, particularly in plethoric habits.—(*Med. Chir. Trans. vol.* 11, *p.* 368.)

In the beginning of the constitutional attack, Pouteau and Dussassoy particularly recommended emetics; and Mr. Briggs, Dr. J. Thomson, and Dr. Hennen are all advocates for this practice, though the latter gentleman makes his evidence rather ambiguous by a subjoined note, in which he mentions, that want of success, &c. led to the trial of venesection.—(*Op. cit.*

222.) As for Mr. Blackadder, he deems the employment of emetics at the commencement of hospital gangrene useful only when the stomach is foul.—(*On Phagedæna Gangrænosa*, *p.* 134.) Dr. Boggie found emetics generally very inferior to purgatives.—(*Edinb. Med. Chir. Trans. vol.* 3, *p.* 37.) He chiefly approves of them when the stomach is loaded, and the fever of a bilious character. In the early stage of the case, writers seem all to agree about the utility of purgative and laxative medicines. When there is debility, good generous wine should be allowed, either by itself or mixed with lemonade, according to circumstances. Bark is in general more hurtful than useful: Mr. Welbank objects to it generally, on account of the common disposition to diarrhœa in the advanced stages of the disease (*Med. Chir. Trans. vol.* 11, *p.* 368); and Dr. Hennen assures us that he has seen great harm done by large and injudicious doses of this drug, before full evacuations had taken place, and the sloughs begun to separate. Boyer allows, however, that it may be beneficially given when the feverish heat has abated, and the debility is very great.

In all stages of this disease, unattended with diarrhœa, acids are proper The sulphuric acid is that which is given with most success; but, the acidulous tartrate of potassa is also an excellent medicine. From two drachms to half an ounce may be given every day, and the best plan is to make an acid drink with it, which should be sweetened and strained.

In severe cases, attended with a quick and feeble pulse, depression, restlessness, and anxiety, an opiate becomes necessary. "So long as we wish to excite a degree of moisture on the skin (says Professor Thomson), Dover's powder, or laudanum with antimonial wine, form in general the best opiates." This gentleman, however, is not an advocate for the employment of opium, in the early stage of hospital gangrene, while the heat and other febrile symptoms are at their height. —(See *Lectures on Inflammation*, *p.* 494, 495.) According to Mr. Welbank's experience, narcotics are beneficial, and he has seen a most irritable state of the stomach improve rapidly, and a foul, furred tongue become clean, on the administration of large doses of opium at regular intervals.—(See *Med. Chir. Trans. vol.* 11, *p.* 368.) Camphor, in large and frequent doses, was highly praised by Pouteau.

From what has been said of internal remedies, it is evident that none of them can be regarded as means at all to be depended upon for arresting the ravages of hospital gangrene, however advantageous they may prove in palliating general symptoms, removing particular complications, enabling the system to support the effects of the local disorder for a greater length of time, or, in a few cases, even placing nature in a condition to throw off the diseased parts herself, and communicate to the subjacent living flesh a healthy action.

If credit can be given to several of the authors who have had the most extensive opportunities of attending to the nature of hospital gangrene, the local treatment is far more effectual than internal medicines.

"I was told by several of the French surgeons (says a late visiter to Paris), that they did not rely at all on internal means for stopping the progress of hospital gangrene, and that their experience had proved them to be insufficient, if not wholly inefficacious. Dupuytren, in reply to the account I gave him of the practice and opinions of English surgeons on this subject, assured me that he had no confidence in any but local applications, and that internal remedies alone, as far as he had found, did almost nothing." The same remark has been made in a modern publication on hospital gangrene (*Delpech, Mém. sur la Complication des Plaies, &c.* 1815), "although it seems to be rather at variance with its being a constitutional and contagious disease, which the author has admitted."—(See *Sketches of the Medical Schools of Paris, by J. Cross*, *p.* 83.)

Perhaps every antiseptic application that can be mentioned has been tried as a dressing for wounds, or ulcers, affected with hospital gangrene. All watery applications, and common poultices, and fomentations, are generally condemned, as inefficacious and even hurtful. Dr. Boggie, however, is an advocate for cold lotions in the incipient inflammatory stage; and, perhaps, solutions of the chlorides of lime and soda may deserve trial.

Dussassoy was convinced, by the observation of numerous cases, that the best application is powder of bark. He recommends the wound to be covered with several layers of this powder, which are then to be moistened with turpentine. When this composition dries, he asserts, that it forms a fragile sort of coat, at the sides of which, and through which, the discharge escapes. After twenty-four hours, the first coat is to be removed, and a fresh one applied. In general, according to this writer, four or five such dressings are sufficient in simple cases, where the disorder is confined to the skin and cellular substance. Healthy inflammation then occurs, the sloughs come away, and the wound puts on a healing appearance. In bad cases, Dussassoy sometimes added one-fifth of powdered muriate of ammonia to the bark. When this treatment failed, the actual cautery was used.

On the subject of bark, as a local application to hospital gangrene, I need only remark, that it is now entirely relinquished, either as possessing no efficacy (*Delpech*), or even aggravating the symptoms (*Blackadder*).

The milder forms of the disease appear sometimes to have yielded to the application of the vegetable and diluted mineral acids; viz. lime-juice, lemon-juice, vinegar, and the diluted nitric and muriatic acids. And the same observation may be made, with respect to solutions of the nitrates of silver and mercury The two latter substances, and the oxygenated muriatic acid, and gas, were found by Dr. Rollo to be capable of effecting a cure. Delpech, in particular, speaks of the benefit derived from the application of strong vinegar, after all the pulpy viscid matter has been carefully wiped away from the surface of the living flesh. The vinegar is then poured on the ulcer, which is to be covered with charpie wet with the same liquid. When the case is too far advanced for this treatment to answer, Delpech tries caustics, especially the nitrate of silver; and if these fail, he has recourse to the actual cautery; and when the sloughs are very thick, so as to hinder the cautery from acting to a sufficient depth, he prefers thrusting into the sloughs, down to the living flesh, angular pieces of caustic potash, at small distances from each other!—(*Précis Elém. des Mal. Chir. t.* 1, *p.* 151.) Surely this must be far more torturing and less certain of success, than removing the sloughs, and applying the cautery.

Though the actual cautery is generally admitted to be one of the most powerful means of stopping the progress of hospital gangrene, the surgeons of this country entertain a strong aversion to the practice; and I confess that my own dislike to it is such as would always lead me to prefer any other treatment, from which equal efficacy would result. At the same time, it must be granted, that if the actual cautery will more certainly arrest some forms of hospital gangrene, than any other known applications, the surgeon's duty is to put out of the question his own prejudices against it, and consider only his patient's welfare. I am far from thinking, however, that while there are such powerful caustics as the undiluted mineral acids, and a dressing so effectual as a solution of arsenic, it can often be absolutely necessary to employ red-hot irons.

The merit of having pointed out in modern times the great efficacy of Fowler's solution of arsenic, or the liquor arsenicalis of the London Pharmacopœia, as an application to phagedæna gangrænosa, belongs to Mr. Blackadder. In answer to the objection, that the external use of arsenic is not unattended with danger, he assures us, that he has heard of but one instance of hospital gangrene, in which any deleterious effects were supposed to arise from the absorption of the arsenic; and the patient in question was very soon cured of his uneasy, and possibly merely nervous symptoms.—(*P.* 50.)

"The first thing to be attended to in every case of disease (says Mr. Blackadder) is *cleanliness*, which, if always of great importance, is in this instance indispensable. The surface of the body ought to be made, and kept, perfectly clean, by means of the tepid bath, or otherwise by a plentiful use of soap; and the linen, and bed-clothes, should be frequently changed, particularly when soiled with matter from the sore." In order to make the sore perfectly clean, and free it from the viscous discharge, without producing considerable bleeding and pain, Mr. Blackadder recommends two large tin hospital teapots to be filled with a

weak solution of the subcarbonate of potass. One of these solutions is to be cold, the other tepid; because sometimes one, and sometimes the other, is found most agreeable to the patient's feelings, though the warm is the most effectual in cleansing the sore. The liquid is to be poured over the sore and received into a basin, which ought to be immediately emptied into another vessel placed at a distance from the patient. During this ablution, the glutinous matter, which adheres to the sore, may be gently detached, by means of small dossils of fine tow or lint; but these (says Mr. Blackadder) should never be used for two different patients, rigid economy, on occasions such as this, being a very mistaken principle. In these cases, the use of sponges (he justly observes) ought to be entirely laid aside, as they can seldom be used more than once with safety. When the sore has been thus cleaned, a piece of fine dry lint is to be spread over its surface, and gently pressed into all its depressions with the points of the fingers. When the lint is removed, a quantity of the discharge will be found adhering to it; and this operation must be repeated with fresh pieces of lint, until the surface of the sore is made perfectly clean and dry.

According to Mr. Blackadder, the solution of arsenic will generally be found strong enough, when diluted with an equal part of water; but in slight cases it answered, when weakened with twice its quantity of water; and, in a few examples, it was employed without being at all diluted. Several pieces of lint of the same shape as the sore, but a little larger, are to be prepared; one of these, soaked in the solution, is now to be applied to the cleaned surface of the sore, and renewed every fifteen or thirty minutes, according to the time in which it becomes dry. When the heat and inflammation are considerable, great relief will be derived from the frequent application of linen cloths, moistened with cold water, which must be kept from weakening the arsenical solution by means of a small piece of oil-skin laid over the pieces of lint. When the disease extends into the track of a gunshot wound, Mr. Blackadder uses a syringe for cleaning the sore and introducing the solution. "A slip of fine lint, well soaked in the solution, may also be inserted, by means of a probe, into the bottom of the wound; and when the openings are at no great distance (from each other), and not in the immediate vicinity of the large nerves and blood-vessels, the lint may be drawn through the wound in the form of a seton."—(*P.* 53.) When the pain caused by the application is very severe, and the constitution is irritable and debilitated, Mr. Blackadder prescribes an opiate, though he remarks, that this practice will seldom be absolutely necessary. The morbid action in the sore is destroyed by the arsenical solution sooner or later in different cases: *the best plan is to continue the application until an insensible, dark-coloured, dry slough occupies the whole surface of the sore, and until the patient is completely relieved from the burning and lancinating pain.*

After the slough is formed, Mr. Blackadder employs an ointment composed of equal parts of the oil of turpentine and the yellow resinous ointment, or of two parts of Venice turpentine to one of the resinous ointment. "These being melted and mixed together are to be poured over the sore, as hot as the patient can possibly bear." A pledget of dry lint or tow, and a bandage, are then applied; and this dressing may be renewed two or three times a day, the sore being each time carefully washed with the solution of potass. As soon as any part of the slough is loosened, Mr. Blackadder removes it with a pair of curved scissors. With the view of expediting the separation of the slough, he sometimes employed a linseed meal poultice, which had the desired effect, but was found to be too relaxing. When it is used, therefore, Mr. Blackadder found it expedient, at each dressing, to touch the new granulations with the nitrate of silver.

After the detachment of the slough, Mr. Backadder dresses the sore with the above-mentioned ointment cold, or with the addition of a small proportion of the subacetate of copper. The pledget of this ointment is covered with a piece of oil-skin, lightly rubbed over with soap, and a firm bandage is applied to the whole limb.—(See *Obs. on Phagedæna Gangrænosa*, *p.* 49, *&c.* 8*vo. Edinb.* 1818.) The author declares, that after the introduction of the above treatment (with the exception of stumps attacked with hospital gangrene), he never saw an instance in which the remedy failed when applied in time and a proper manner; "that is, before the disease had made such progress as to preclude all rational hope of success from that or any other mode of treatment."—(*P.* 23.)

In Doctor Rollo's Treatise on Diabetes, published in 1797, the opinion is plainly stated, that the progress of hospital gangrene might be stopped by very active topical applications, and, in the same work, Mr. Cruikshank says, that if an actual caustic were to be employed, we should have recourse to the strong nitrous acid." According to Mr Blackadder, the oxygenated muriate of mercury, and the nitrous acid, were much recommended and employed by surgeons in the 16th and 17th centuries, as escharotics in cases of gangrene and foul ulcers.—(*P.* 113.) Several army surgeons have informed me that the undiluted nitrous acid was successfully used as an application to hospital gangrene in the military hospitals at Antwerp, in the year 1815; but that other strong acids had an equally good effect. Dr. J. Thompson also notices, that "the application of caustic substances, such as the strong mineral acids, the solutions of potass, corrosive sublimate, and arsenic, seemed at Antwerp to arrest the progress of this sore, without exciting inflammation."—(*Report of Observations made in the Military Hospitals in Belgium.*)

Delpech was informed by some British surgeons, belonging to the Anglo-Portuguese army in the peninsula, that the muriatic acid was in common use in the hospitals of that army, as a local application for checking the ravages of hospital gangrene, being employed in a diluted state for slight cases, and in a concentrated caustic form for others.

In St. Bartholomew's Hospital, the undiluted nitric acid has been used with great success as a local application to phagedenic gangrenous ulcers. "If the disease be not far advanced (says Mr. Welbank), I at once apply the undiluted acid, after cleansing the surface with tepid water, and absorbing the moisture with lint. Where, however, there is a thick and pulpy slough, it is better to remove as much of it as possible, with forceps and scissors before the application is made. The surrounding parts being then protected by a thick coating of lard, or cerate, I proceed to press steadily, and for some minutes, a thick pledget of lint, previously immersed in the undiluted acid, on every point of the diseased surface, till it appears converted into a firm and dry mass. The parts may be then covered with simple dressings, and evaporation kept up by cooling lotions. As the application occasions more or less pain, from half an hour to one or two hours, I have generally given 20 or 30 drops of laudanum at the time of using it. It is always prudent, often necessary, to remove the eschar at the end of 16 or 20 hours." When the patients have become perfectly free from pain, and the parts below the slough are found healthy and florid, Mr. Welbank treats the sore as a common wound or ulcer, though he has found stimulating dressings generally the best, as the ceratum lapidis calaminaris, or a solution of two or three grains of the nitrate of silver in an ounce of distilled water. But when there is a recurrence of pain at any point, or over the general surface of the sore, whether the affection be slight or severe, the slough superficial or deep, he recommends the employment of the undiluted acid again.—(See *Med. Chir. Trans. vol.* 11, *p.* 369.)

Pouteau, Dussassoy, Boyer, and Delpech, all bear testimony to the efficacy of the actual cautery, and they repeat the application of it, until the whole surface of the ulcer is converted into a firm hard eschar. Even the edges of the solution of continuity should not be spared—"*Ils doivent être torréfiés et rôtis pour ainsi dire.*"—(*Boyer, Traité des Maladies Chir. t.* 1, *p.* 332.) The latter surgeon then covers the eschar with a thick stratum of bark, moistened with turpentine. This application is to be removed, in twenty-four, thirty-six, or forty-eight hours, and the surgeon is then to judge from the appearance of the flesh, and the quality of the discharge, whether a further repetition of the cautery will be necessary.

About three years ago, I attended, at Halliford, a child that had been extensively burnt; and when the parts were nearly healed, the sore was attacked with hospital gangrene, the ravages of which soon proved fatal. The cottage in which this case happened was noted for its crowded and uncleanly state.

HYDRARGYRIA. A peculiar eruption occasioned by the use of mercury, and named in Dr. Bateman's Synopsis *eczema rubrum*. (See *Mercury*.)

HYDROCELE. (From ὕδωρ, water, and κήλη, a tumour.) The term *hydrocele*, if used in a literal sense, means any tumour containing water; but surgeons have always confined it to a collection of fluid either in the cellular membrane of the scrotum; in a cyst, or the common cellular texture, of the spermatic cord; or in the tunica vaginalis of the testicle.

The celebrated Dr. Alexander Monro of Edinburgh, and Mr. S. Sharp, were almost the only writers, before Mr. Pott, who sensibly and rationally explained the true nature of these diseases.

ANASARCOUS TUMOUR OF THE SCROTUM.

The *hydrocele by infiltration* of French writers; *hydrocele œdematodes*; is most frequently only a symptom of a dropsical habit, and very often accompanies both anasarca and the particular collection within the abdomen called ascites. Mr. Pott describes it as "an equal soft tumour, possessing every part of the cellular membrane, in which both the testicles are enveloped, and consequently it is generally as large on one side as on the other; it leaves the skin of its natural colour, or, to speak more properly, it does not redden or inflame it; if the quantity of water be not large, nor the distention great, the skin preserves some degree of rugosity; the tumour has a doughy kind of feel; easily receives, and for a while retains, the impression of the fingers; the raphe, or seam, of the scrotum divides the swelling nearly equally: the spermatic process is perfectly free, and of its natural size; and the testicles seem to be in the middle of the loaded membrane. This is the appearance, when the disease is in a moderate degree. But if the quantity of extravasated serum be large, or the disease farther advanced, the skin, instead of being wrinkled, is smooth, tense, and plainly shows the limpid state of the fluid underneath: it is cold to the touch, does not so long retain the impression of the finger, and is always accompanied with a similar distention of the skin of the penis; the preputium of which is sometimes so enlarged, and so twisted and distorted, as to make a very disagreeable appearance. These are the local symptoms: to which it may be added, that a yellow countenance, a loss of appetite, a deficiency of urinary secretion, swelled legs, a hard belly, and mucous stools, are its very frequent companions."

As the cellular membrane on one side of the scrotum is a continuation of that which is situated on the other, and both freely communicate, the accounts, delivered by certain authors, of the possibility of this species of hydrocele being confined to one side of the scrotum, are not credited by Boyer. At all events, such a case is extremely rare, and when it happens, is probably induced by the irritation of the urine in infants, or of the friction of the clothes in old persons, only acting upon a part of the scrotum; for occasionally, though not often, the disease is acknowledged to proceed from these local causes.—(See *Dict. des Sciences Méd. t.* 22, *p.* 193.)

The cure of the original disease, when it arises from constitutional causes, comes within the province of the physician, and requires a course of internal medicine; but sometimes the loaded scrotum and penis are so troublesome to the patient, and in such danger of mortification, that a reduction of their size becomes absolutely necessary. As Mr. Pott observes, the means of making this discharge are two, viz. puncture and incision: the former is made with the point of a lancet; the latter with the same instrument, or with a knife. Wounds in anasarcous or dropsical habits are apt to inflame, are very difficultly brought to suppuration, and often prove gangrenous. But the larger and deeper the wounds are, the more probable are these bad consequences. Simple punctures, with the point of a lancet, are much less liable to be attended by them, than any other kind of wound: they generally leave the skin easy, soft, cool, and uninflamed, and in a state to admit a repetition of the same operation if necessary. Incisions create a painful, crude, hazardous sore, requiring constant care. Punctures seldom produce any uneasiness at all, and stand in need of only a superficial pledget for dressing.

As the cavities of the cellular membrane of the scrotum all communicate together, a small puncture serves, as well as a large incision, for the discharge of the fluid contained in them, and consequently, upon this ground, no reason exists for making any extensive, painful, and hazardous wound.

With respect to the practice of making punctures, in cases of anasarcous hydrocele, I think that it should always be avoided as much as possible; because it sometimes happens, that the slightest pricks of the lancet occasion sloughing. The method should only be adopted, when the distention of the skin of the scrotum is such as absolutely to require the fluid to be discharged. Care should also be taken not to multiply the punctures unnecessarily, nor to let them be made too near together. Boyer had a case, in which the making of very slight punctures in an anasarcous scrotum, was followed by the total destruction of this part, denudation of the testis and cord, and the patient's death attended with dreadful suffering.—(See *Dict. des Sciences Méd. t.* 22, *p.* 195, 196.)

When the œdematous state of the scrotum is not the effect of a general constitutional disease, but proceeds entirely from a local cause, such as friction, or the irritation of the urine, the mode of treatment consists in the removal of the cause, the use of astringent lotions, and the exhibition of a dose of salts. In elderly subjects the wearing of a bag-truss is recommended for the prevention of the complaint.

HYDROCELE OF THE SPERMATIC CORD

Is of two kinds: the first is described as an œdematous affection, extending to more or less of the cellular substance round the spermatic vessels, and sometimes named the *diffused hydrocele of the cord*; the second form of the disease is that in which the fluid is collected in a particular cavity or cyst, which has no communication with the cavities of the common cellular substance of the cord. This case is denominated, accordingly, the *encysted hydrocele of the cord*. The cellular substance, situated behind the bag of the peritoneum, surrounds the spermatic vessels, passes with them through the inguinal ring, and accompanies them to their insertion in the testicle. As Scarpa has likewise explained in his great work on hernia, the spermatic vessels, their cellular sheath, and the tunica vaginalis are all enclosed in the musculo-aponeurotic sheath of the cremaster. When a *diffused hydrocele* of the spermatic cord is dissected, the sheath of the cremaster is found under the integuments, varying in size and compactness according to the duration and bulk of the disease. Under it appears the cellular covering of the cord, thickened, distended with fluid, and seeming at first somewhat like a hernial sac. When cut, a great deal of serum is discharged, and the tumour sinks and disappears in a greater or less degree. The spermatic vessels, which had been previously concealed by

the enlarged cellular mass, now become visible. The cells, which, in their natural state, are scarcely perceptible to the unassisted eye, are found to have become vesicles filled with fluid, and some of them are large enough to receive the end of a finger. When the tumour is large and of long standing, the cells are remarked to become more delicate towards its bottom, and in this situation disappear, only one large cavity filled with fluid being here found. Hence, according to Scarpa, a fluctuation is plainly distinguishable at the lowest part of the swelling. The serum contained in the cells is generally limpid; but sometimes yellow, albuminous, or gelatinous. The base of the swelling, however large or old it be, corresponds to the point, at which the spermatic vessels join the testis, or, at most, it extends a very little behind this organ, and between the two there is a semicircular groove, which varies in depth and extent. Scarpa farther informs us, that if the tunica vaginalis be opened, a dense septum is felt at its inner and lower part, cutting off all communication between this sac and the base of the tumour.—(*Memoria sull' Idrocele del Cordone Spermatico*, 4*to*. *Pavia*, 1823.)

That the cellular membrane of the cord is often distended with an aqueous fluid, when the scrotum is anasarcous, and the habit dropsical, cannot admit of doubt; and hence it is a frequent attendant on the case, which has been described as the hydrocele œdematodes. But as I have never seen an instance, in which such disease was restricted to the cellular texture of the cord, I am led to suppose that it is a very uncommon case. The following is said by Mr. Pott to be the state of the disease, while of moderate size. The scrotal bag is free from all appearance of disease; except that when the skin is not corrugated, it seems rather fuller, and hangs rather lower on that side than on the other, and if suspended lightly on the palm of the hand, feels heavier: the testicle, with its epididymis, is to be felt perfectly distinct below this fulness, neither enlarged, nor in any manner altered from its natural state: the spermatic process is considerably larger than it ought to be, and feels like a varix, or like an omental hernia, according to the different size of the tumour: it has a pyramidal kind of form, broader at the bottom than at the top: by gentle and continued pressure it seems gradually to recede or go up, but drops down again immediately upon removing the pressure; and that as freely in a supine, as in an erect posture: it is attended with a very small degree of pain or uneasiness; which uneasiness is not felt in the scrotum, where the tumefaction is, but in the loins.

According to Scarpa, its shape is at first nearly cylindrical, and does not become pyramidal till afterward. However large the swelling may be, the penis never appears so much retracted under the integuments of the pubes as in a common hydrocele of equal size. When the lower part is compressed, the fluid recedes towards the groin slowly and difficultly, while, in the hydrocele of the tunica vaginalis, the same kind of pressure at once forces the fluid to the apex of the tumour, and distends it, and the testis cannot be felt (as in the diffused hydrocele) below the swelling.

When a diffused hydrocele of the cord extends into the ring, it is not easily distinguished from an omental hernia. In both cases, says Scarpa, the tumour is at first of a cylindrical shape, and afterward becomes pyramidal; both kinds of swelling are soft and flexible, both little, if at all, sensible; and both admit of reduction with difficulty. No doubt, the best criterion of the hernia, if it be reducible, will be derived from the circumstance of its generally not reappearing, while the patient continues to lie down, though Scarpa has seen a few exceptions.

While it is small, it is hardly an object of surgery, and may be kept from being troublesome by means of a suspensory; but when it is large, it is very inconvenient both from size and weight, and, according to Pott, the only method of cure which it admits, viz. that of making a free incision into the swelling, is far from being void of hazard. This is especially true, when the disease is complicated with constitutional disorder. Thus Pott and Scarpa have known the inflammation consequent to an extensive incision have a fatal termination. As the cavities of the cellular texture, in which this hydrocele forms, all communicate together, it appears to me, that the necessity of a free incision for the discharge of the fluid is not so manifest as the observations of Pott would lead us to suppose; and that a moderate opening would be likely to answer every purpose, with much greater safety.

THE ENCYSTED HYDROCELE OF THE SPERMATIC CORD

Is by no means unfrequent, especially in children. The same kind of disease also sometimes occurs in the round ligament of the uterus, and accompanies it through the abdominal ring. It was very well known to many of the ancients, and has been accurately described by Albucasis, Celsus, Paulus Ægineta, &c. When Mr. Pott says that the disease is not unfrequent, it ought to be understood, that its frequency, though much greater than that of the diffused hydrocele of the cord, considered as a distinct disease independent of general anasarca, is not at all equal to that of the hydrocele of the tunica vaginalis. Richerand has calculated, that the average proportion of encysted hydroceles of the cord to those of the latter description, is not more than as one to two hundred.—(*Nosogr. Chir. t.* 4, *p.* 262, *ed.* 4.) According to Mr. Pott, the swelling is mostly situated at the middle part of the cord, between the testicle and groin, and is generally of an oblong figure. Whether it be large or small, it is generally pretty tense, and consequently the fluctuation of the water within it not always immediately or easily perceptible. It gives no pain, nor (unless it be very large indeed) does it hinder any necessary action. It is perfectly circumscribed; and has no communication, either with the cavity of the belly above, or that of the vaginal coat of the testicle below it. The testis and its epididymis are perfectly and distinctly to be felt below the tumour, and are absolutely independent of it. The upper part of the spermatic process in the groin is most frequently very distinguishable. The swelling does not retain the impression of the fingers; and, when lightly struck upon, sounds as if it contained wind only. It undergoes no alteration from change of the patient's posture; it is not affected by his coughing, sneezing, &c.; and it has no effect on the discharge per anum.

Scarpa observes, that the diagnosis is more difficult when the encysted hydrocele is of considerable bulk, because the testis is buried, as it were, in the tumour. Here, says he, if that portion of the swelling which projects forwards and somewhat laterally at its lower part, be softish, smooth, and very sensible, while the rest presents the character of a collection of fluid, the first and smaller portion is the testis in its healthy state; and the other portion an encysted hydrocele of the cord. This kind of hydrocele may be known from scirrhus of the testis by its consistence, smoothness, and freedom from pain.

The two diseases, however, with which this kind of hydrocele is most likely to be combined are, a hydrocele of the tunica vaginalis, and a hernia. The characters in which it differs from the first have been already noticed.

According to Pott, the free state of the upper part of the spermatic cord, while the tumour is forming below; the gradual accumulation of the fluid, and consequently the gradual growth of the swelling; the indolent and unaltering state of it; its being incapable of reduction, or return into the belly from the first; its being always unaffected by the patient's coughing or sneezing; and the uninterrupted freedom of the fecal discharge per anum, will always distinguish it from an intestinal hernia. Its liability to be mistaken for an omental hernia, and its characteristic difference, I have already mentioned.

Mr. Pott met with an encysted hydrocele, situated so high towards the groin, as to render perception of the spermatic vessels very obscure, or even impracticable; but then, the state and appearance of the testicle, and the absence of every symptom proceeding from confinement of the intestinal canal, were sufficient marks of the true nature of the complaint.

The cyst is described by Scarpa as consisting of two layers; first, the sheath of the cremaster, and under it the cellular structure of the cord, more or less thickened. The under surface is irregular, fringed, and in some places villous.

In general, the pressure of an encysted hydrocele pushes the testis a little lower in the scrotum than natural, and rather forwards. Scarpa found this organ, however, in one instance, considerably wasted, and adherent to the tunica vaginalis.

Several writers describe this kind of hydrocele as in fact a common encysted tumour, formed in the cellular substance, between the vas deferens and spermatic vessels.—(*Delpech, Précis Elém. des Mal. Chir. t.* 3, *p.* 464.) Yet, since ordinary encysted swellings are very difficult to disperse, there is probably some difference between the two affections; at least, if the observation of Mr. Pott be correct, that in young children the encysted hydrocele of the cord frequently dissipates in a short time, especially if assisted by warm fomentation and an open belly.

If it be not absorbed, "the point of a lancet will give discharge to the water; and in young children, will most frequently produce a cure: but in adults, the cyst formed by the pressure of the fluid does sometimes become so thick, as to require division through its whole length; which operation may in general be performed with great ease and perfect safety." Mr. Pott says in general, because it is most frequently so; though he has seen even this, slight as it may seem, prove troublesome, hazardous, and fatal.

The late Sir J. Earle proposed treating this case in the same way as the hydrocele of the tunica vaginalis, viz. by an injection of red wine and water; which method is often successful.—(*On Hydrocele, p.* 154, *edit.* 2.) However, the cure of an encysted hydrocele of the spermatic cord, by means of an injection, is generally regarded by modern surgeons as less certain and advantageous than the excision of a part of the cyst. The operation, which is described by Bertrandi, Mr. Hey, Richerand, &c., consists in cutting down to the cyst, and removing the fore part of it, while the portion, closely attached to the cord, is to be allowed to remain. (For additional observations on this species of hydrocele, see the *First Lines of the Practice of Surgery, ed.* 5, *p.* 528.)

HYDROCELE OF THE TUNICA VAGINALIS.

If the quantity of limpid fluid, which naturally moistens the surface of the tunica albuginea and the inside of the tunica vaginalis, be secreted in an undue quantity, or if regular absorption of it be by any means prevented, it will gradually accumulate, and distend the cavity of the latter membrane, so as to form the present species of hydrocele. The case in which the fluid is supposed to descend either partly or entirely from the cavity of the abdomen, in consequence of the communication not being shut up in the usual time between the cavity of the peritoneum and that of the tunica vaginalis, is well known to surgeons under the appellation of a congenital hydrocele; a disease, of which particular notice has been taken in the 2d vol. of the fourth edition of the *First Lines of Surgery, 8vo. Lond.* 1820, and to which I shall therefore very briefly advert in this article. Hydrocele of the vaginal coat is a disease from which no time of life is exempt: not only adults are subject to it, but young children are frequently afflicted with it, and infants sometimes born with it.—(*Pott.*) It is also remarked to be common in old men, and persons who ride a good deal on horseback.—(*Delpech, Précis Elém. des Mal. Chir. t.* 3, *p.* 177.)

The causes of hydrocele of the tunica vaginalis can scarcely be said to be at all understood; and when Mr. Pott observes, that whatever tends to increase the secretion of fluid into the cavity of that membrane, beyond the due and necessary quantity, or to prevent its being taken up and carried off by the absorbent vessels, must contribute to the production of the disease, nearly as much is stated, as can be advanced with safety in the present state of our knowledge. Ruysch had a suspicion, that this hydrocele might arise from a varicose state of the spermatic veins; but though Mr. Pott acknowledges, that these vessels are very frequently found varicose in patients afflicted with this disorder, he was unable to pronounce what real foundation might exist for the foregoing conjecture, or whether the varicose state of the spermatic veins were a cause or an effect of the hydrocele. In most instances, the accumulation of fluid takes place without any evident cause; though, in a few cases, it has appeared to be the effect of a contusion, or of rough, long-continued friction of the scrotum. The disease is observed to affect persons of the best health and most robust constitutions, as well as others; and its existence seems quite unconnected with dropsy or debility. In short, it may be regarded as a disease entirely of a local nature. As Mr. Pott observes, its production is so slow and gradual, and at the same time so void of pain, that the patient seldom attends to it until it is of some size. Sometimes, however, it is produced very suddenly, and soon attains considerable magnitude.

In general, at its first beginning, the tumour is rather round; but as it increases, it frequently assumes *a pyriform kind of figure, with its larger extremity downwards:* sometimes it is hard, and almost incompressible; so much so, that, in some few instances, it has been mistaken for an induration of the testicle: at other times, it is so soft and lax, that both the testicle and the fluid surrounding it are easily discoverable. It is perfectly indolent in itself, and may be rather strongly pressed without pain; though its weight sometimes produces some small degree of uneasiness in the back. According to Mr. Pott, the transparency of the tumour is the most fallible and uncertain sign belonging to it: it is a circumstance, says he, which does not depend upon the quantity, colour, or consistence of the fluid constituting the disease, so much as on the uncertain thickness or thinness of the containing bag, and of the common membranes of the scrotum.

If they are thin, the fluid limpid, and the accumulation made so thick as not to give the tunica vaginalis time to thicken much, *the rays of light may sometimes be seen to pass through the tumour:* but this is accidental, and by no means to be depended upon. The fluid is most frequently of a pale yellow or straw colour; sometimes it is inclined to a greenish cast; sometimes it is dark, turbid, and bloody; and sometimes it is perfectly thin and limpid. According to Boyer, the colour of the fluid makes no difference in the prognosis; and he tells us, that, by means of an injection, he cured a hydrocele that contained a violet-coloured fluid, which deposited a thick sediment.—(*Dict. des Sciences Méd. t.* 22, *p.* 214.) When a hydrocele has existed for a very long time, cartilaginous bodies are sometimes found in the fluid.—(*Sir A. Cooper, Lancet, vol.* 2, *p.* 79.)

With respect to Mr. Pott's remarks on the transparency of the swelling, as a symptom of hydrocele, they are correct, inasmuch as the absence of this sign is no proof that the disease is not of this nature; since thickness of the tunica vaginalis, and, as ought also to have been admitted, the opaque quality of the fluid, sometimes prevent the rays of a candle from passing through the swelling. But on the other hand, it should have been explained by Mr. Pott, that *when the transparency is present, it is one of the surest marks of this species of hydrocele.*

A thickened state of the vaginal coat is chiefly met with in old cases, and, according to Sir Astley Cooper, in patients who have long resided in hot climates.—(See *vol. cit. p.* 46.)

It is next noticed by Mr. Pott, that in the beginning of the disease, if the water has accumulated slowly, and the tunica vaginalis is thin and lax, the testicle may easily be perceived; but if the said tunic be firm, or the water accumulated in any considerable quantity, the testis cannot be felt at all. In most cases, the spermatic vessels may be distinctly felt at their exit from the abdominal muscle, or in the groin; which will always distinguish this complaint from an intestinal hernia. But in a few examples, the vaginal coat is distended so high, and is so full, that it is extremely difficult, nay, almost impossible, to feel the spermatic cord: and the same kind of obscurity is sometimes occasioned by the addition of an encysted hydrocele of the cord; or by the case being combined with a true enterocele.

In a hydrocele of the tunica vaginalis, *the swelling is first noticed at the lower part of the scrotum,* whence it ascends in front of the testicle and spermatic cord. The progress of the disease is generally so slow, that six or even eighteen months elapse before the tumour approaches the abdominal ring. And among other characters of the case, are to be noticed the disappearance of the corrugations of the scrotum by the effect of the distention; inclination of the raphe to the opposite side; a diminished appearance of the penis, from a good deal of its integuments being drawn over the hydrocele, when this is bulky; the great lightness of the swelling, in relation to its size; and the possibility of feeling *a fluctuation,* when the fingers of one hand are applied to one side of the tumour, and the surgeon slightly taps with the fingers of his other hand upon an opposite point of the swelling.

With respect to the fluctuation, however, it is, in

Boyer remarks, sometimes evident, sometimes obscure, and, in other instances, not distinguishable at all.—(*Dict. des Sciences Méd. t.* 22, *p.* 200.) These differences depend much on the quantity of fluid, and the thickness or thinness of the vaginal coat.

In the hydroceles of children, the testis occupies a lower situation than the same organ in the hydroceles of adult persons, and the swelling passes farther up towards the abdominal ring. The hydrocele, in fact, is in them situated rather in front of the cord, than the testis, which is always at the lower and back part of the swelling.—(See *Dict. des Sciences Méd. t.* 22, *p.* 199.) The common situation of the testis is two-thirds of the way down the tumour at its posterior part. But, as Sir Astley Cooper has correctly explained, a great deal of irregularity, in this respect, is met with, the testis being sometimes in front of the hydrocele; a circumstance, arising from the existence of adhesions between the middle and outer coat of that organ at its fore part, previously to the formation of the hydrocele. The testis is sometimes found at the bottom of the swelling, as is exemplified in a preparation shown by the same gentleman, where the fluid had been prevented from descending below and in front of the testis, by the middle and outer coats of that organ being so connected together by the adhesive inflammation. He has one specimen in which the fluid was situated only at the sides of the testis, adhesions having prevented its accumulation at other points; and another, in which the hydrocele seems as if it had arisen from the tunica vaginalis, in the same manner as an aneurismal sac is occasionally formed from the coats of an artery.—(See *Lancet, vol.* 2, *p.* 78.) These facts prove the necessity of always endeavouring to learn the precise situation of the testis by manual examination, before an operation is attempted. When the surgeon presses rather strongly on that organ, he will feel the part much firmer than the rest of the tumour, and the patient complains of a severe and peculiar pain.

A hydrocele of the tunica vaginalis may be complicated with disease of the testis, hernia, cirsocele, hydrocele of a hernial sac, or encysted hydrocele of the cord.

A collection of fluid in the tunica vaginalis, complicated with a scirrhous or chronic induration and enlargement of the testicle, is well known under the name of *hydro-sarcocele:* a case which should be carefully discriminated from a simple hydrocele; "one of the marks of the latter being the natural, soft, healthy state of the testicle, and the characteristic of the former being its diseased and indurated enlargement."

Mr. Pott does not mean, that in a true simple hydrocele the testicle is never altered from its natural state. He admits the contrary, and that it is often enlarged in size, and relaxed in structure, and that the spermatic vessels are frequently varicose. But the testicle is not indurated. These two diseases are extremely unlike each other, and require very different treatment. That which would cure a simple hydrocele, would dangerously aggravate the hydro-sarcocele.

Mr. Pott observes, that it may, and does, sometimes become necessary to let out the water from the vaginal coat of a testicle in some degree diseased; but this should always be done with caution, and under a guarded prognostic; lest the patient be not only disappointed by not having that permanent relief which, for want of better information, he may be induced to expect; but be also (possibly) subjected to other unexpected inconveniences from the attempt.

According to Richerand, a hydrocele may be known from a sarcocele by the following circumstances: in a sarcocele, the tumour mostly retains the shape of the testicle, being oval, and a little flattened at the sides, and its size becomes considerable in a short time, without ascending so near the abdominal ring as a hydrocele does when of the same magnitude. A large hydrocele leaves no interspace between that opening and the tumour, so that it is difficult to take hold of and lift up the spermatic cord; but in a sarcocele there is always a space between the tumour and the ring, where the cord can be distinctly felt. Lastly, in a sarcocele the tumour is always opaque, and its weight, in reference to its size, much more considerable than that of a hydrocele.—(*Nosogr. Chir t.* 4, *p.* 267, *ed.* 4.) The latter disease generally only produces inconvenience by its bulk, or the excoriations sometimes caused between the scrotum and the thigh; but a diseased testis occasions dragging pains in the loins and neighbouring hip. The hardness is not a symptom which can be trusted alone as a criterion of a diseased testicle; for when a hydrocele is extremely distended, it often feels so indurated as to deceive practitioners of great experience, and a thickened, hardened state of the tunica vaginalis may facilitate the mistake. In some instances of *hydro-sarcocele*, the nature of the disease sometimes remains questionable until the evacuation of the fluid gives the surgeon a fair opportunity of ascertaining the diseased state of the testicle.

The complication of a hydrocele of the tunica vaginalis with an encysted one of the spermatic cord may generally be known by the swellings having begun at two different points, and by a kind of constriction between them. The latter symptom, however, is not infallible, because the tunica vaginalis of a common hydrocele is sometimes more or less contracted at the middle of the tumour, which is thus made to appear as if there were two distinct pouches.

When there are two swellings, and one admits of being pushed into the abdominal ring, the case is probably complicated with a rupture.—(See *Hernia.*)

The size of a hydrocele, and the thickness of the tunica vaginalis, are generally in a ratio to the time which the disease has continued. Sometimes the latter membrane acquires nearly a cartilaginous hardness; and portions of it have been found in an ossified state; the only circumstance in which any free excision of it is now accounted necessary. A hydrocele has been known to contain four pints of fluid.—(*Voigtel, Handbuch, der Pract. Anat. b.* 3, *p.* 388.)

TREATMENT OF THE HYDROCELE OF THE VAGINAL COAT.

A hydrocele is by no means a dangerous complaint, though its weight and size are a disagreeable encumbrance, and the patient is always obliged to wear a bag-truss, in order to prevent a painful extension of the spermatic cord. Troublesome excoriations are also frequently caused by the friction of the tumour against the inside of the thigh; and when the swelling is very large, it draws over itself the integuments of the penis, which appears buried, as it were, in the tumour, and its functions are seriously interrupted. Hence, the greater number of patients are very anxious for relief.

Cases are sometimes met with in which an accidental inflammation and sloughing of the scrotum are followed by the discharge of the fluid, an obliteration of the cavity in which it had collected, and a permanent cure.—(See *Lancet, vol.* 2, *p.* 81.) The accidental rupture of a hydrocele by violence, however, does not always lead to a radical cure: one instance is mentioned by Sir Astley Cooper, in which the fluid collected again; and another is quoted by him, in which the blow only changed the hydrocele into hæmatocele. —(*Op. cit. p.* 83.)

"The methods of cure (says Pott), though various, are reducible to two: (viz.) the palliative, or that which pretends only to relieve the disease in present, by discharging the fluid: and the radical, or that which aims at a perfect cure, without leaving a possibility of relapse. The end of the former is accomplished by merely opening the containing bag in such manner as to let out the water; *that of the latter cannot be obtained unless the cavity of that bag be abolished, and no receptacle for a future accumulation left* (which proposition, though generally true, is subject to exceptions, as the observations of Mr. Ramsden and Mr. Wadd, published since Mr. Pott's time, tend to prove). One may be practised at all times of the patient's life, and in *almost* any state of health and habit: the other lies under some restraints and prohibitions, arising from the circumstances of age, constitution, state of the parts, &c.

"The operation by which the fluid is let out is a very simple one. The only circumstances requiring our attention in it are, the instrument wherewith we would perform it; and the place or part of the tumour into which such instrument should be passed.

"The two instruments in use are the common bleeding-lancet and the trocar.

"The former having the finer point, may possibly pass in rather more easily (though the difference is hardly perceptible), but is liable to inconveniences,

to which the latter is not. The trocar, by means of its cannula, secures the exit of the whole fluid without a possibility of prevention; the lancet cannot. And therefore it frequently happens, when this instrument is used, either that some of the water is left behind, or that some degree of handling and squeezing is required for its expulsion; or that the introduction of a probe, or a director, or some such instrument, becomes necessary for the same purpose. The former of these may in some habits be productive of inflammation: the latter prolongs what would otherwise be a short operation, and multiplies the necessary instruments; which, in every operation in surgery, is wrong. To which it may be added, that if any of the fluid be left in the vaginal coat, or insinuates itself into the cells of the scrotum, the patient will have reason to think the operation imperfect, and to fear that he shall not reap even the temporary advantage which he expected. The place where this puncture ought to be made is a circumstance of much more real consequence; the success of the attempt, the ease, and even sometimes the safety of the patient, depending upon it."

As the testicle is usually situated at the upper and back part of the cavity of the hydrocele, or, according to Sir Astley Cooper, about two thirds of the way downwards, at the posterior part of the swelling, the trocar should generally be introduced at the fore part of the tumour, and directed obliquely upwards. However, this rule is subject to all the difference which must proceed from the great varieties sometimes met with in the position of the testicle, and already specified. Nothing can be more certain, than the truth of Sir Astley Cooper's remark, that the trocar never can be introduced with safety, unless the exact situation of that gland has been first ascertained. Whether the operation be done for the palliative or radical treatment, the trocar is to be withdrawn the instant the cannula enters the tunica vaginalis; but care must be taken to hinder the tube from slipping out, or rather to prevent the tunica vaginalis from slipping off it, which is best guarded against by holding the tube steadily within the puncture, and keeping the tunica vaginalis tense by grasping the tumour at its back part, until the operation is finished.—(See *Lancet*, *vol.* 2, *p.* 81.)

After performing this operation, a bit of lint and soap plaster is generally applied; and if the scrotum has been considerably distended, it is to be suspended in a bag-truss.

In most people, the orifice heals in a few hours (like that made for blood letting); but in some habits and circumstances, it inflames and festers: this festering is generally superficial only, and is soon quieted by any simple dressing; but it sometimes is so considerable, and extends so deeply, as to affect the vaginal coat, and by accident produce a radical cure. Mr. Pott also saw it prove still more troublesome, and even fatal; but then the circumstances, both of the patient and of the case, were particular. Two examples are mentioned by Sir Astley Cooper, in which gangrene arose from the puncture, and ended fatally: the patients were elderly persons, who had imprudently ventured to walk out the day after the operation.—(*Lancet*, *vol.* 2, *p.* 82.) Hence the prudence of advising quietude in bed for a few days, when the patients are of advanced age, or of irritable constitutions.

"Wiseman and others have advised deferring the puncture till a pint of fluid has collected. When there is a sufficient quantity, however, to keep the testicle from the instrument, there can be no reason for deferring the discharge; and the single point on which this argument ought to rest is this: Whether the absorbent vessels by which the extravasation should be prevented are more likely to reassume their office while the vaginal coat is thin, and has suffered but little violence from distention; or after it has been stretched and distended to ten or perhaps twenty times its natural capacity; and by such distention is (like all other membranes) become thick, hard, and tough? Mr. Pott thinks the probability so much more on the side of the former, that he should never hesitate a moment about letting out the water as soon as he found that the puncture could be made securely. And from what has happened within the small circle of his own experience, he is inclined to believe, that if it were performed more early than it generally is, it might sometimes prevent the return of the disease."

The foregoing passage deserves to be particularly recollected, because it evidently implies a belief by Mr Pott himself, that, under certain circumstances, a radical cure may be effected, though the cavity of the tunica vaginalis be not obliterated; an opinion since promulgated, as I have already said, by Mr. Ramsden, Mr. Wadd, and Mr. Kinder Wood. Indeed, it appears probable, that generally when a hydrocele is permanently cured by means of such external applications as do not excite inflammation, but operate by quickening the action of the absorbent vessels, the cavity of the tunica vaginalis is not destroyed; and there can be but little doubt of the same thing whenever what is termed a spontaneous cure happens, as it sometimes does in young subjects. It used also to be the doctrine of Desault, that injections did not obliterate the cavity of the hydrocele by adhesion, but only brought about a change in the vessels of the tunica vaginalis. This conclusion is reported by Boyer to be erroneous, who had an opportunity of dissecting the scrotum after a hydrocele had been radically cured, and the cavity was found obliterated.—(See *Dict. des Sciences Méd. t.* 22, *p.* 206.) Now, although our present information leads us to regard the latter as the common result, it does not authorize us to reject the inference made by Desault: in fact, Sir A. Cooper dissected a case, which he cured several years previously by an injection; yet there were only a few adhesions, and the removal of the disease must be ascribed to some change effected in the vessels of the tunica vaginalis.—(See *Lancet*, *vol.* 2, *p.* 84.)

The palliative cure is sometimes deemed most eligible for very old persons. Its repetition will be necessary once every six months, or even much more frequently, if the fluid collect again very rapidly, and produce great distention, as sometimes happens. It should in general be performed at least once on those who determine to undergo a radical one, as it gives an opportunity of examining the state of the testis, and also of permitting the cavity to be filled again only to such a size, as may be thought to be best calculated to ensure success in any future operation.—(*Sir J. Earle on Hydrocele*, *p.* 13, *ed.* 2.)

Upon the subject of performing the operation of tapping hydroceles, Scarpa offers some useful cautions. The analogy which exists between large scrotal herniæ and hydroceles of considerable size, led this writer to suspect, that, in the latter disease, the displacement and separation of the vessels of the spermatic cord from each other might also happen. Careful investigations, made upon the dead subject, fully justified the conjecture. In all considerable hydroceles, he found the spermatic vessels so displaced and separated, and that the artery and vas deferens were ordinarily situated on one side of the tumour, and the veins on the other. Sometimes these vessels all extended over the lateral parts of the tumour, as far as its anterior surface, principally towards the bottom.

It is well known, that, in many instances, the operation of puncturing a hydrocele has been followed by a large extravasation of blood within the tunica vaginalis; but Scarpa informs us, that until lately, he was unacquainted with any case of this kind, which was well detailed, and authentic enough to be cited as an example of injury of the spermatic artery in the puncture of a hydrocele. This learned professor, however, has had such a fact recently communicated to him by Gasparoli, a distinguished surgeon of Pallanza, who, in introducing the trocar into the lower part of the swelling, had the misfortune to injure the spermatic artery, and the patient was afterward castrated. The wound of this vessel was most clearly proved by the particulars of the case, as detailed in Scarpa's work, to which I must refer the reader.

"From the accurate knowledge (says Scarpa) which we now have upon this pathological point, such an accident may be avoided, by observing the rules, which are elsewhere given, for opening the sac of a very large scrotal hernia. In this last operation, as well as that of puncturing an old and voluminous hydrocele, care must be taken to introduce the instrument at a considerable distance from the bottom of the tumour, that is to say, a little below its middle part, and on a line which would divide the swelling longitudinally into two perfectly equal parts. Experience proves, that for the purpose of completely emptying a hydrocele, it is unnecessary to make the puncture very near the bottom of the tumour. The corrugation

of the scrotum, and a slight pressure, made by the surgeon's hand, will suffice for discharging all the fluid contained in the tunica vaginalis, even when the puncture is made at the middle part of the swelling."—(*Scarpa, Traité des Hernies, p.* 64—68.) On account of the lower situation of the testicle in the hydrocele of a child than in that of a grown-up person, these directions of Scarpa will also be of value.

RADICAL CURE OF THIS HYDROCELE.

Besides the employment of external applications, wherewith a permanent cure has occasionally been accomplished, on the principle of absorption, six different operations have been practised for the same purpose: viz. incision; excision; the application of caustic; the introduction of a tent; the employment of a seton; and the injection of a stimulating fluid into the cavity of the tunica vaginalis.

The principle, on which the success of these plans is commonly believed to depend, is the excitement of such a degree of inflammation within that cavity, as leads to the production of adhesions, or granulations, whereby its obliteration is affected, and, of course, no receptacle for a future accumulation of fluid remains.

In the preceding columns, however, I have noticed the possibility of a cure, even though the cavity may not be completely annihilated.

All the above plans are not equally eligible. Some of them, indeed, are now quite exploded; and some, which are still practised by a few, are not more successful, though certainly more severe, than one which will be presently recommended; while others are very uncertain in their effect, as well as painful.

Incision.

Making an incision, so as to lay open the cavity containing the fluid, is the most ancient method, being described by Celsus. Paulus Ægineta says, the incision is to commence at the middle of the tumour, and be carried to the upper part of it, in a line parallel to the raphe. This incision is only to go through the integuments; the bag, which contains the water, is then to be opened, and part of the sides of the sac taken away. A director is next to be introduced, and a division of the tunica vaginalis made to the bottom of the swelling. The cavity is afterward to be dressed with lint, and healed by granulations. Hildanus Dodonæus, Wiseman, Cheselden, Heister, and Sharp, all coincide in stating the dangerous and even fatal consequences sometimes following this mode. Mr. B. Bell, who preferred this operation to every other one, acknowledges that he has seen it produce great pain and tension of the abdomen, inflammation, and fever. Pott observes, that it can never be said to be totally void of danger, and that it bears the appearance of an operation of some severity. This eminent surgeon abandoned the method, during the last twenty-six years of his life. Sir A. Cooper mentions one case, in which it proved fatal in an elderly person.—(*Lancet, vol.* 2, *p.* 86.) Severe as it is, it has also been known to fail, as Sabatier and Earle have seen.

Excision.

Albucasis gave the first clear account of this operation, though Celsus has certainly mentioned removing some of the sac. White and Douglas used to adopt this method. The latter advises making two incisions, so as to form an oval, from the upper to the lower part of the tumour; dissecting off the oval piece of the scrotum, and then making an opening into the sac, and enlarging it with scissors. The tunica vaginalis was next to be entirely cut away, close to where it was connected with the spermatic vessels. The cavity was afterward filled with lint. Sir James Earle justly notices that this plan must have been tedious, exquisitely painful in the performance, and, as subsequently treated, attended with violent and dangerous symptoms. Sir Astley Cooper informs us, that the last time he saw this operation performed, a violent inflammation and sloughing of the scrotum ensued.—(See *Lancet, vol.* 2, *p.* 84.) In modern days, excision is only sanctioned, when the tunica vaginalis is more or less in an ossified state, for a mere thickening of it does not prevent the success of milder plans of treatment. With respect to a mode of excision, recently proposed by Mr. Kinder Wood, it differs entirely from the ancient method, inasmuch as it is perhaps the mildest of every plan yet suggested for the radical cure, since it simply consists in puncturing the hydrocele with an abscess lancet, drawing out a little bit of the sac with a tenaculum, and cutting it off.—(See *Med. Chir. Trans. vol.* 9, *p.* 33.) But farther experience is requisite to determine whether this very easy plan is as certain as that with an injection. Whether the cavity is obliterated or not, as Mr. Kinder Wood himself believes, appears also still questionable

Caustic.

Paulus Ægineta advises destroying the skin with a cautery of a particular form, dissecting off the eschar, and then cauterizing the exposed membrane. Guido di Cauliaco is, perhaps, the first who described the application of caustic for the cure of hydrocele. Wiseman practised this method. Dionis advises it; but De la Faye and Garengeot make objections to it. Mr. Else has left the best account of the manner of using caustic. He recommends laying "a small caustic upon the anterior and inferior part of the scrotum, which is intended to affect, and, if possible, penetrate through the tunica vaginalis."

The objections to the employment of caustic are, its causing an unnecessary destruction of parts, and producing a tedious painful sore. The action of caustic can never be so regulated as to make an opening with certainty through the tunica vaginalis, so that either its application must sometimes be repeated, or else a lancet or trocar used after all. Its success is also less sure than that of an injection. In one case, operated upon by Boyer, the disease returned; and in another example, in the practice of the same surgeon, the cure was accomplished at a great risk, as it was long dubious whether the testis would be saved.—(*Dict. des Sciences Méd. t.* 22, *p.* 210.) An instance of death from the use of caustic is mentioned by Sir A. Cooper in his valuable lectures.—(See *Lancet, vol.* 2, *p* 85.)

Tent.

This was first mentioned by Franco. The operation consists in making an opening into the tunica vaginalis, and keeping the wound open with a tent of lint, linen, or sponge, so as to make the cavity suppurate, in which the water was contained. Paré, Guillemau, Covillard, Ruysch, Heister, and Marini have all described the plan, with some variations, one of which consisted in smearing the tents with irritating substances. Dr. A. Monro senior devised the plan of keeping a cannula in the tunica vaginalis, so as to bring on a cohesion of the parts, without suppuration. Fabricius ab Aquapendente, however, has made allusion to some surgeons before his time, who used to keep the wound open a few days with a cannula. Mr Pott tried the cannula, but found it very inconvenient, as its inflexibility hurt the testis whenever the patient moved with inattention, and, consequently, he preferred a tent or bougie, though he speaks of the plan as a very uncertain one.

Of late, Baron Larrey, in consequence of having seen several instances, in which the symptoms, following the use of an injection, were violent, and one case in which a fatal peritonitis was produced, has recommended exciting the necessary degree of inflammation by keeping a short piece of an elastic gum catheter in the puncture, which instrument also serves afterward to let any fluid escape from the tunica vaginalis.—(*Mém. de Chir. Militaire, t.* 3, *p.* 409, *&c.*) This author, of course, speaks of the plan as having fully answered his expectations; but I much doubt whether it has any particular superiority over several of the former methods of employing the tent; methods, which the wisdom, arising from experience, has long since rejected.

Seton

Was first mentioned by Guido di Cauliaco, in 1498, as a means of curing the hydrocele. In modern times, Pott preferred it to every other method, if we except injection, of which, according to Sir J. Earle, he expressed his approbation before his decease. Sir A. Cooper still retains a preference to the seton for children, on account of its application being more easy in them than the employment of injection.—(*Lancet, vol.* 2, *p.* 85.) Mr. Pott found, that the best mode of making the seton was as follows. He employed three instruments: the first was a trocar, the cannula of which was about one-fourth of an inch broad. The second was what he called the seton-cannula, which was

made of silver, was just small enough to pass with ease through the cannula of the trocar, and five inches long. The third instrument was a probe six inches and a half long, having at one end a fine steel trocar point and at the other an eye, which carried the seton. The seton consisted of so much white sewing silk, as would just pass easily through the cannula, and yet fill it. The thickness of the seton, however, was not so great in the latter part of his practice. Having pierced the inferior and anterior part of the tumour with the trocar, withdrawn the perforator, and discharged the water, Mr. Pott used to pass the seton-cannula through that of the trocar, to the upper part of the tunica vaginalis, so as to be felt there. The probe, armed with the seton, was next conveyed through the latter cannula, and its point pushed through the upper part of the tunica vaginalis and scrotum. The silk was then drawn through the cannula, until a sufficient quantity was brought out of the upper orifice. The two cannulæ being withdrawn, the operation was finished.

Injection.

Dr. Monro attributes the first use of injections for the radical cure of hydroceles to an army surgeon of his own name, who employed spirit of wine. This produced a cure; but the inflammation was so violent, that he afterward tried a milder injection, which consisted of wine. However, Lambert in his *Œuvres Chir.*, published at Marseilles early in the seventeenth century, advised injecting a solution of sublimate in lime water, and he has related cases of success. Mr. S. Sharp also made trial of spirit of wine, which cured the hydrocele, but not without causing dangerous symptoms, and two subsequent abscesses in the scrotum.—(*Operations of Surgery.*) Douglas, Le Dran, and Pott, all disapprove of injections in their works; though Sir James Earle informs us, that the latter lived to alter his opinion on the subject.

The violence of the inflammatory symptoms, consequent to the first employment of injections for the radical cure of hydroceles, arose from the fluids used being too irritating. Sir James Earle, at last, preferred wine for several reasons. He found that it had been used with success in France; its strength is never so great as to render it unsafe; and it may be readily weakened. However, as the strength and other qualities of port wine vary considerably, Sir A. Cooper prefers using a solution of the sulphate of zinc, 3j to a pint of water.—(*Lancet, vol.* 2, *p.* 87.)

"I have commonly used (says Sir James Earle) about two-thirds of wine to one-third of water: if the parts appeared insensible, and no pain at all was produced by the first quantity thrown in, I have withdrawn the syringe, and added to the proportion of wine: on the contrary, if the complaint was recent, and the parts irritable, I have increased the proportion of water; so that I have hitherto been principally guided by the degree of sensation which the patient has expressed. I have lately used pure water mixed with wine, and found it answer as well as when astringents were added."—(*Treatise on the Hydrocele, p.* 103, *ed.* 2.) In the preface, the author says, that he has long disused the pipe with a stop-cock, which he once employed, on account of not being well able to spare a hand, during the operation, to turn it, and its consequently being found awkward. A pipe, one end of which is made to fit into the cannula of a trocar, the other adapted to receive the neck of an elastic bottle, with a valve or ball in the centre of the pipe, to permit the entrance and prevent the exit of the injection, will be found infinitely more convenient and useful.—(*Earle.*) When the hydrocele is very large, Sir James recommends simply letting out the fluid, and waiting until the tumour acquires a more moderate size before attempting the radical cure by injection.

It appears from Sir James Earle's interesting cases, that a cure may be accomplished in this manner, even when the tunica vaginalis is considerably thickened. In the course of a month, Boyer cured a patient with an injection, even though the testicle was enlarged.—(See *Dict. des Sciences Méd. t.* 22, *p.* 214.) Similar cases are also reported in the *Parisian Chir. Journ.* The following is the common mode of operating: the hydrocele is to be tapped with a trocar at its anterior and inferior part, and when the whole of the fluid is evacuated, the cavity of the tunica vaginalis is to be distended to its former dimensions with the above injection. This is to be allowed to remain in the part about five minutes, upon the average, after which it is to be discharged through the cannula. The patient usually feels some pain in the groin, and about the kidneys, on the injection being introduced; which symptoms are rather desirable, as they evince, that the stimulus of the fluid is likely to have the wished-for effect of exciting the necessary degree of inflammation. This plan, which was brought to a high pitch of perfection by the late Sir James Earle, may be deemed almost a sure means of obtaining a permanent cure; and being at the same time mild, is mostly preferred in England, France, and Germany.

The treatment after the operation is exactly like that of the common swelled testicle (see *Hernia Humoralis*), consisting of the use of fomentations, poultices, leeches, saline purges, and, above all, of a bag truss for keeping up the scrotum. However, a strict antiphlogistic treatment need not be adopted, unless the inflammation become too violent, because a certain degree of it is necessary for the cure. Sometimes, Sir A. Cooper even recommends his patients, when the inflammation is not brisk enough, to take wine, live well, and walk about. According to Boyer, the occasional failure of the treatment with injections is owing to the premature discontinuance of spirituous applications, and the too quick substitution of emollients for them, as well as the plan of not letting the injection remain in the tunica vaginalis long enough.—(See *Dict. des Sciences Méd. t.* 22, *p.* 213.)

One caution it is necessary to offer before taking our leave of this subject. It has sometimes happened during the operation, that the cannula has slipped out of the tunica vaginalis, and its inner mouth become situated in the substance of the scrotum, in which event the operator, if he persists in propelling out the injection, will fill the cellular texture of the part with a stimulating fluid, which may cause abscesses, sloughing, and other unpleasant symptoms, without entering the cavity of the tunica vaginalis, or producing a radical cure of the hydrocele, which, however, I have known happen from this cause, as I have elsewhere related.—(See *First Lines of Surgery, vol.* 2.) When such an accident happens, it is better to defer the operation till a sufficient quantity of fluid has collected again. Sometimes, when the injection is strong, a great deal of it has passed into the cellular membrane, and the constitution is irritable, the mischief produced ends in the patient's death. Many such cases are on record, and two are noticed by Sir A. Cooper.—(See *Lancet, vol.* 2, *p.* 89.)

Hydroceles have been cured by applying to the scrotum a solution of muriate of ammonia in vinegar and water.—(*Keate.*) But the application frequently creates a good deal of pain and irritation, and, in grown-up persons, does not often succeed, to say the best of it.—(*Earle.*) However, in young persons and children, the employment of brisk purgatives, discutient lotions, and a suspensory bandage, mostly proves successful, as is confirmed by the testimony of Sir Astley Cooper.—(*Lancet, vol.* 2, *p.* 83.)

Distending the tunica vaginalis with air, cold water, or even the fluid discharged, has sometimes effected a radical cure.—(See *Supplement to Ploucquet, p.* 103, *Tub.* 1814.)

A case is mentioned by Sir A. Cooper, in which milk was injected, on the supposition of its being a mild, unirritating fluid: however, very severe inflammation followed, and an abscess in the tunica vaginalis. When an opening was made, the milk came out in curds.

There is a particular case, that has been called the *congenital hydrocele*, by which is implied a collection of water in the tunica vaginalis, with a communication between the cavity of this membrane and that of the peritoneum. Desault used to cure this disease by a red wine injection. After the protruded viscera had been returned into the belly, and while the opening between that and the inside of the tunica vaginalis was carefully compressed and closed by a trusty assistant, Desault, after letting out the water in the common way, used to throw in the injection. The method, it is said, succeeded, without causing the perilous consequence one might *à priori* expect, viz. inflammation of the peritoneum.

This kind of hydrocele has not been described by

many writers. The case is easily distinguished by the fluid being capable of being pushed into the belly. By means of a vinous injection, Desault cured a boy both of a congenital hydrocele and hernia.—(See *Œuvres Chir. de Desault*, *t.* 2, *p.* 442.)

The method which I should recommend is the constant application of a truss; by which means Sir A. Cooper has known a cure very successfully accomplished.—(See *Lectures*, *vol.* 2, *p.* 91.)

HYDROPHOBIA. (From ὕδωρ, water, and φόβος, fear. *A dread of water.*) This being, for the most part, a striking symptom of the fatal indisposition which results from the bite of a mad dog, and some other animals affected in the same way, the disease itself has been named *hydrophobia*. Some have used the more general term, *hygrophobia*, from ὑγρὸν, liquid. But strong objection has been made to both these terms, because derived from a symptom which does not exclusively belong to the disease, nor constantly exist in it.

The old writers, as we learn from Cælius Aurelianus, used the terms *aërophobia*, or *a dread of air*, and *pantephobia*, or *a fear of all things*, since the impression of cold air sometimes excites terror, and the disorder is marked by a singular degree of general timidity and distrust. Others called it *phobodipson* (δίψος signifying thirst), because the patient is *thirsty*, yet *fears* to drink. Several modern authors, however, objecting to any appellation expressive only of one symptom, denominate the disease *rabies*, and *rabies canina*, or canine madness. The French call it *la rage*.

With respect to hydrophobia, or the dreadful indisposition produced by the bite of a dog, or other animal, affected with rabies, or by the application of some of the secretions of such animal to a part of the body, the first clear mention of it is generally considered to be that made by Aristotle (*Hist. Animal. lib.* 7, *cap.* 22); but he could have had but very erroneous notions upon the subject, since he sets down man as incapable of receiving the distemper from the bite of a rabid dog.

Concerning the antiquity of hydrophobia, however, I particularly refer to Dr. Hecker's Observations, who thinks the fact clearly proved, that the disease existed at least 400 years before Christ, and even in the most remote periods.—(See *Jour. für Chir. von C. F. Graefe, &c. b.* 2, *p.* 325, *&c.*)

With respect to a name for the disorder, as the patient does not commonly betray any tendency to fury, while the dread of water is really a customary attendant on the complaint, the terms *rabies* and *la rage* seem strictly even more exceptionable than the word hydrophobia. At the same time, in order not to imbibe confused notions, whatever name be thought fittest for the illness arising in the human subject from the bite of a mad dog, and some other animals similarly affected, it is necessary to understand well, that hydrophobia, *in the sense of a horror of water or other liquids*, is an occasional symptom of many diseases, and neither exclusively confined to the indisposition caused by the bite of a rabid dog, or certain other animals, nor even constantly attendant upon it. And, with the same view of avoiding perplexity, all hydrophobic complaints may be arranged in two general divisions.

1. The first comprising all cases not ascribable to the bite of a rabid animal, or the application of some of its secretions to a part of the body.

2. The second comprehending the examples preceded by one of those occurrences.

The cases included in the first of these divisions are subdivided into the *symptomatic* and *idiopathic* or *spontaneous*. By *symptomatic hydrophobia* is understood an aversion or dread of liquids, presenting itself as an occasional symptom of various diseases, as of certain inflammatory, febrile, and nervous disorders, hysteria, epilepsy, injuries of the brain (*Trecourt, in Recueil Périodique, &c. t.* 6; *Acta Naturæ Curios. vol.* 2, *obs.* 205), the operation of particular poisons (*Villermay, Traité des Mal. Nerveuses, t.* 1, *p.* 90; *Harles, über die Hundiswuth, Frankf.* 1809; *Schmiedel, Diss. de Hydrophobiâ ex Usu Fructuum Fagi, Erlang.* 1762, *&c.*), gastritis, pneumonia, hepatitis, angina, &c. &c. In many of the instances of symptomatic hydrophobia, the aversion or dread of fluids occurs on the same day as the cause upon which it depends, or a few days afterward; and, for the most part, may be cured with the disease which has given rise to it, or even independently of it. On the contrary, the hydrophobia from the bite or infection of a rabid animal, does not come on till a long time after the occurrence of the cause, and when once formed, has hitherto proved incurable. Whatever analogy, therefore, may be imagined to exist between symptomatic hydrophobia and rabies, they differ essentially in their causes, progress, degree of curability, and also in the treatment required. —(See *Dict. des Sciences Méd. t.* 4, *p.* 38.)

Spontaneous or *idiopathic* hydrophobia denotes the questionable form of the complaint, sometimes supposed to be induced by violent mental commotion, anger, fright, &c. unpreceded by any other primary disease, to which it can be referred as a symptom.

Numerous facts upon record leave no doubt concerning the reality of symptomatic hydrophobia; but, perhaps, none of the cases adduced by Raymond (*Mém. de la Soc. Royale de Méd. t.* 2, *p.* 457), Roupe (*Nova Acta Physico-Med. t.* 4), or Pouteau (*Essai sur la Rage, Lyons*, 1763), in proof of the possibility of a spontaneous idiopathic form of the disease in the human subject, are sufficiently unequivocal to remove all suspicion, either that the complaint had been preceded by another primary disease (*Dict. des Sciences Méd. t.* 22, *p.* 333), or had been the result of an unobserved or forgotten occasion, on which the infection was received from handling a dog or cat, never suspected at the time to be affected with rabies. Here a wrong conclusion is the more apt to be made, in consequence of the disease being communicable without any bite to fix the patient's attention, and not commencing sometimes for months after the unnoticed receipt of the infection. Thus, Francis Stannier died, in Nov. 1787, with symptoms of hydrophobia, though it was not known that he had ever been bitten by a mad dog (*Lond. Med. Journ. vol.* 9, *p.* 256); yet, what safe inference can be drawn from this case, when the above-mentioned circumstances are recollected, and it is known that the man was often drunk, and in the streets at night? These and other considerations even throw a doubt upon a part of the cases, recorded as instances of symptomatic tetanus, and they lead the generality of modern writers to incline to the sentiment of Dr. J. Hunter, that a disease similar in its nature to what is produced by the bite of a mad dog, never arises *spontaneously* in the human subject.—(See *Trans. of a Soc. for the Improvement of Med. and Chir. Knowledge*, *vol.* 1, *p.* 299—303.) Many of the symptomatic cases, however, or those in which more or less aversion or dread of liquids is evinced as an effect of another disease, are too well authenticated to admit of doubt. In the *Dict. des Sciences Méd. t.* 22, *art. Hydrophobie*, may be found a great deal of information likely to interest such readers as wish to follow up the subject of the symptomatic forms of the disease. However in

looking over some of the cases there detailed, a suspicion will sometimes arise in an intelligent mind, that the disorder was mistaken; for it will be noticed, that sometimes pain shooting up the limbs preceded the general indisposition, while the rapidity of the disease, and the appearances found on dissection, corresponded precisely to what is usually remarked in hydrophobia. In particular, one patient is described as a man habituated to drinking, and, as *a sportsman, to dogs also*: he died on the third day, and on dissection, the stomach and intestines were found inflamed, and even gangrenous in several places, the œsophagus and lungs also participating in the inflammation.—(*Commerc. Litter. Noremb.* 1743, *hebd.* 5.)

Animals of the dog kind, including the wolf and the fox, are most frequently the subjects of rabies; and certain writers have maintained, that although it may be received and propagated by other animals, yet it always originates in some of the canine race.—(*Hillary on Diseases of Barbadoes*, *p.* 246.) However, it is asserted, that the disease sometimes originates spontaneously in cats, that is to say, without their having been previously bitten by another rabid animal; but the moderns do not incline to the belief, that it ever has been known to commence in this manner in other animals, though such an assertion is made by Cælius Aurelianus, Porphyrius, Avicenna, Valeriola, Vander Wiel, &c. not only with respect to man, but horses, asses, camels, hogs, bullocks, bears, monkeys, and even poultry.—(See *Dict. des Sciences Méd. t.* 47, *p.* 45.)

It is interesting to inquire, what animals are capable of communicating rabies, and what animals of receiving it? As far as our knowledge yet extends, it appears, that animals of the canine species, with perhaps those of the feline race, are the only ones in which this disorder ever arises spontaneously, and they may transmit it to animals of their own kind, to other quadrupeds, and to man. The experiments made by Dr. Zincke, tend to prove also that birds, at least the common fowl, may have the disease communicated to them.—(*Neue Ansichten der Hundswuth, &c.* 8*vo. Jena*, 1804.)

But though it be well known that animals of the dog and cat kinds can propagate the disorder, it is not settled, whether it can be communicated by other animals. In a memoir, read to the French Institute, M. Huzard explained, that herbivorous quadrupeds affected with rabies, are incapable of transmitting the disease; a position subsequently confirmed by additional experiments and observations made in the veterinary school at Alford. M. M. Girard and Vatel inoculated with the saliva of a rabid sheep two other sheep, a young dog, and a horse; but none of these animals evinced any symptoms of the disease, and continued well four months after the experiment.—(*Magendie, in Journ. de Physiol. Expér. t.* 8, *p.* 326, *&c.* 8*vo. Paris*, 1828.) Professor Dupuy could never communicate the distemper to cows and sheep, by rubbing their wounds with a sponge, which animals of the same class, already labouring under the disease, had had in their mouths; though the same experiment, made with a sponge which had been bitten by a rabid dog, propagated rabies by a kind of inoculation. Dupuy has likewise seen, among several flocks, sheep affected with rabies, yet the distemper was never communicated by them to other sheep, notwithstanding the latter were bit in parts stripped of wool. Dr. Gillman inoculated two rabbits with the saliva of a rabid pig; but the disease was not communicated to them.—(*On the Bite of a Rabid Animal*, *p.* 38.) On the other hand, Mr. King, of Clifton, is stated to have communicated rabies to a fowl by inoculating it with the saliva of an ox, which had just fallen a victim to the disease.—(*J. Ashburner, Diss. de Hydrophobiâ*, *p.* 29.) The author of the article *Rage* (*Dict. des Sciences Méd.*) observes, respecting this singular case, that, as it is accompanied with no details, doubts must remain, whether the fowl actually died of rabies. A fatal instance of hydrophobia from the bite of a rabid badger has been lately recorded, though not with such precision as to leave no doubts about the nature of the case.—(See *Hufeland's Journ. for* 1821.)

As for some extraordinary cases, in which the disease is alleged to have been communicated to the human subject by the bites of birds, or injuries done with the claws of animals, they are generally dismissed by modern writers, with the inference, that the complaint thus transmitted was not true hydrophobia or rabies. This conclusion is made with respect to the cases of this kind reported by Cælius Aurelianus and Bader, and the notorious example mentioned by A. Baccius, of a gardener who died of the bite of a cock, which, according to some, was rabid, according to others, merely enraged. Hildanus also details an instance, in which a young man was scratched on the great toe by a cat; and, some months afterward, was attacked with hydrophobia (*Obs. Chir. cent.* 1, *obs.* 10): but, as a modern writer observes, if the patient were really affected with rabies, it is conceivable that the cat's claw, with which the scratch was made, might have been wet with the animal's saliva.—(*Dict. des. Sciences Méd. t.* 47, *p.* 47.)

Another question of considerable importance is, whether hydrophobia, that is to say, rabies, can be communicated from one human being to another? or, whether, in man, the disease is infectious or contagious? Many attempts have been made, in vain, to communicate the distemper to several kinds of animals, by inoculating them with the saliva of patients who had perished of the disease. These experiments were made in this country by Gauthier, Vaughan, Babington, &c.; but no infection was the consequence. In France, Girnud inoculated several dogs with the saliva of a man in the convulsed stage of hydrophobia, but none of them afterward took the distemper.—(*Bosquillon, Mém. sur les Causes de l' Hydrophobie, in Mém. de la Soc. d'Emulation, cinquième annee.*) M. Girard, of Lyons, collected some of the frothy saliva the instant it was discharged from a patient's mouth, and he inserted some of it into eight punctures, made on the inside of a dog's fore legs; yet six months after this inoculation, the animal had not suffered the slightest inconvenience.—(*Essai sur le Tetanos Rabiens*, *p.* 29.) A similar experiment was made on three dogs by M. Paroisse, who kept the animals between three and four months afterward, during all which time they continued quite unaffected.—(*Bibl. Méd. t.* 43.)

Dr. Bezard published the following experiments: pieces of the flesh of a person who had died of hydrophobia, were smeared with his saliva, and given to a dog: another dog was suffered to eat the salivary glands; and a third the sides of a wound. In three other dogs, incisions were made: the cut parts were then inoculated, and sewed up. Not one of these six animals became affected with rabies.—(See *Mém et Obs. lus à la Soc. Méd. Philanthropique, première année*, 1807, *p.* 17.)

The preceding experiments only furnish negative results; but one, to which we shall now advert, tends to establish a contrary opinion. On the 19th June, 1813, in the Hôtel-Dieu at Paris, Magendie and Breschet took some of the saliva of a man, who died a few minutes afterward of hydrophobia, and by means of a bit of rag, they conveyed this saliva to the short distance of twenty paces from the patient's bed, and inoculated with it two healthy dogs. One of the dogs became rabid on the 27th of July, and bit two others, one of which was attacked with complete rabies on the 26th of August.—(*C. Busmou*, see *Collect. des Thèses, in* 4*to. de la Faculté de Paris*, 1814.) It is remarked, in the work from which I have collected these particulars, that the foregoing is one of the best authenticated experiments on the subject; for, in addition to the consideration of the talents and characters of the experimenters themselves, the facts were witnessed by numerous medical students. And notwithstanding the objections which have been urged against the account (see *Journ. Gén. de Méd. t.* 52, *p.* 13), the main points are declared to be entitled to credit.—(See *Dict. des Sciences Méd. t.* 47, *p.* 48. Also *Journ. de Physiologie par F. Magendie, t.* 1, *p.* 42.)

With these relations, it is proper to notice certain cases, too credulously promulgated as proofs of the possibility of the disease being communicated from one human being to another. Neither the instance of the maid-servant, who died merely from seeing her mistress vomit while labouring under hydrophobia (*Mich. Ettmuller, Op. Méd. t.* 2); the case of the peasant's children, *who all died on the seventh day*, as is alleged, from embracing their dying father; the example of a woman contracting hydrophobia from her husband, as detailed by Mangor (*Acta Soc. Reg. Hafniens, vol.* 2, *obs.* 32, *p.* 408); nor other cases of a similar tenour

are now regarded as proving any thing more, than that the patients, supposed to have caught the disease by contagion, fell victims either to violent affections of the mind and nervous system, or illnesses accidentally taking place soon after the death of a near relation or mistress. It is clear enough also, that some of the cases were, at most, only instances of symptomatic hydrophobia.

With regard to another opinion, that the bite of a man or other animal, when merely enraged, may bring on hydrophobia, it is now entirely discarded as erroneous. The cases in support of it, recorded by Cl. Pouteau, Mangetus, Malpighi, Zuinger, Le Cat, &c., when critically examined, only prove that the patients were affected with tetanus or symptomatic hydrophobia, not arising from any infection; for, neither the mode of attack, nor the progress of the symptoms, in any of the examples, which are related with sufficient minuteness, lead to the inference, that the patients actually died of rabies.—(See *Dict. des Sciences Méd. t.* 47, *p.* 49.)

Wrong notions, of a very dangerous tendency, have been generally entertained in regard to the disease, as it appears in the canine race. The writer of the article *Dog*, in Dr. Rees's Cyclopædia, appears to have had extensive opportunities of observing the disorder in dogs: from his remarks I have collected the following information.

The peculiar symptom which often attends the complaint in the human subject, has been applied to the disease in the dog, and has occasioned it to be called by the same name, hydrophobia. This is a palpable misnomer; for in no instance does there ever exist any dread of water: on the contrary, dogs are in general very greedy after it. Neither have sheep, when rabid, any dread of water, but frequently take it with great freedom, as is proved by some experiments, of which an account is given in Magendie's Journal.—(*T.* 8, *p.* 328.) Such unfounded supposition has often conduced to a very fatal error: for, it being the received opinion, that no dog is mad who can lap water, many persons have been lulled into a dangerous security. Another equally false and fatal idea has prevailed, that every mad dog must be wild and furious; but this is so far from being true, that in the greater number of instances there is very little of that wild, savage fury that is expected by the generality of persons. "Hence," says this author, "as it is evident that the term hydrophobia, characterizing the affection in the dog, is a misnomer, so it is evident that the term madness is equally so. In no instance have I ever observed a total alienation of the mind; in very few have the mental faculties been disturbed. The disposition to do mischief is rather an increased irritability than absence of sense; for, in most instances, even those that are furious acknowledge the master's voice, and are obedient." The symptom which is most frequently first observable in a rabid dog is a certain peculiarity in his manner; some strange departure from his usual habits. In a very great number of instances the peculiarity consists in a disposition to pick up straws, bits of paper, rag, threads, or the smallest objects which may happen to be on the floor. This is said to be particularly common in small dogs. "Others again show an early peculiarity by licking the parts of another dog. In one instance the approach of the disease was foretold by our observing a very uncommon attachment in a pug-puppy towards a kitten, which he was constantly licking; and likewise the cold nose of a healthy pug, that was with him. An attachment to the sensation of cold appears in many cases, it being very common to observe them (the dogs) licking the cold iron, cold stones, &c. Some dogs, early in the disease, will eat their own excrement, and lap their own urine." An early antipathy to strange dogs and cats is very commonly observed, but particularly to cats. As the disease advances, the affected dogs bite those with which they are domesticated, and, lastly, the persons around; but, except in a moment of irritability, they seldom attack the human subject. The irritability that induces them to bite is very strong; but is devoid of wildness. It is more like peevishness than fury. A stick held up at them always excites their anger in a violent degree, and throughout the disease there is generally a wonderful impatience of control, and the animals are with great difficulty frightened.—(See *art. Dog, in Rees's Cyclopædia.*) In sheep, as well as dogs, a peculiar change of the voice is regarded as one of the most unequivocal signs of the distemper.—(See *Magendie's Journ. de Physiol. Exp. t.* 8, *p.* 330.)

Dr. John Hunter calculated, that out of every dozen of rabid dogs about one evinces no particular tendency to bite. That these animals, and wolves also, have no particular dread of fluid, is proved by facts. Thus, a rabid wolf, at Frejus, swam across several rivers.—(*Darluc, Recueil Périod. d'Observ. vol.* 4.) Duboueix has seen mad dogs drink without difficulty, and plentifully.—(*Hist. de la Soc. de Méd. an.* 1783.) Rabid animals will sometimes eat as well as drink. Thus, the wolf which bit so many persons at Meyne, in 1718, was found in the morning devouring a shepherd's dog. And Dr. Gillman speaks of a dog which was not deemed rabid because it eat and drank well: but, as it seemed indisposed, it was killed, though not before it had bit a man, who fell a victim to hydrophobia.—(*On the Bite of a Rabid Animal, p.* 15.)

When a dog bites a person, it should not be immediately killed, but merely chained up, because by destroying it at once, the possibility of ascertaining whether it was rabid is prevented, and great alarm is thus kept up in the minds of the wounded person and his friends If the animal be affected with rabies it will perish in a few days. At the veterinary school at Alfort, when a dog has been bit, it is usual to chain it up for at least fifty days before it is restored to its master, about six weeks being considered the period when a dog generally becomes rabid after being bitten.

My friend Mr. St. Aubyn had a large Newfoundland dog, however, which did not become rabid till seventy days had elapsed from the period when it was bitten by another dog. As I saw this case, and am minutely acquainted with the particulars, I consider it as furnishing a useful caution against placing too much confidence in the plan adopted at the veterinary school at Alfort.

For additional details, relating to the disease as it appears in the dog, I must refer to the above-mentioned paper. Enough, I hope, has been said, to make the reader aware, that mad dogs are not particularly characterized by an inability to lap water, nor by any degree of fury. These animals, when actually affected with rabies, from their quiet manner have even not been suspected of having the disorder, and have been allowed to run about, been fondled, and even slept with.—(See *Mem. of Swedish Acad.* 1777.)

The causes of this peculiar distemper in dogs are at present unknown, and little more than conjecture prevails upon the subject. It is not positively known whether rabies sometimes originates spontaneously in these animals, though I believe this opinion is at present gaining ground; or whether, like small-pox in the human species, it is propagated only by contagion. That the disease is frequently imparted, in consequence of one dog biting another, every body well knows; yet there are many instances in which this mode of propagation cannot be suspected. Several facts render it probable, that among dogs, the disease is often communicated by contagion. It is observed, that in insular situations dogs are seldom affected, and this circumstance is ascribed to such animals being in a kind of quarantine. The celebrated sportsman, Mr. Meynell, secured his dogs from the malady, by making every new hound perform a quarantine before he was suffered to join the pack.—(See *Trans. for the Improvement of Med. and Chir. Knowledge, vol.* 1, *art.* 17.) Great heat was very commonly supposed to be an exciting cause of the disease in dogs; but without much foundation. "A very hot climate, or one exposed to the extremes of heat and cold; a very hot and dry season; feeding upon putrid, stinking, and maggoty flesh; want of water; worms in the kidneys, intestines, brain, or cavities of the nose," are set down by Boerhaave as causes of the disease.—(*Aphorism,* 1134.) We learn from Dr. J. Hunter, that in the hot island of Jamaica, where dogs are exceedingly numerous, not one was known to go mad during forty years.—(*Trans. for the Improvement of Med. Knowledge, loc. cit.*) Cold weather has also been set down as conducive to rabies among the canine race, as is suggested, because, the ponds being frozen, these animals cannot quench their thirst.—(*Le Roux.*) That neither of these sentiments about heat and cold being the cause of the origin of the disease in dogs, is correct, will be manifest enough to any body who has patience to look over the volume of the *Mém. de la Soc. Royale de Méd.*

devoted entirely to the consideration of rabies; and from the investigations of M. Andry (*Recherches sur la Rage*, 8vo. *Paris*, 1780), it appears, that January, the coldest month in the year, and August, the hottest, are those which furnish the fewest instances of hydrophobia. On the contrary, the greatest number of rabid wolves is in March and April; and that of dogs affected with spontaneous rabies, in May and September.

According to Savary, dogs never go mad in the island of Cyprus, nor in that part of Syria which is near the sea; and Volney assures us, that these animals enjoy the same fortunate exemption both in the latter country and in Egypt.—(*Voyage in Syrie, t.* 1.) The traveller Brown also declares, that in Egypt they are never, or very rarely, attacked with rabies.

"Although (says Baron Larrey) hydrophobia is more frequent in warm than temperate climates, it is not observed in Egypt; and the natives assured us that they knew of no instance in which this disease had manifested itself either in man or animals. No doubt this is owing to the species and character of the dogs of this country, and their manner of living.

"It is remarked, that the Egyptian dogs are almost continually in a state of inaction: during the day they lie down in the shade, near vessels full of fresh water prepared by the natives. They only run about in the night-time: they evince the signs and effects of their love but once a year, and only for a few instants. They are seldom seen coupled. On our arrival, there was a vast number of these animals in Egypt, because they were held, like many others, in great veneration, and were never put to death. They do not go into the houses: in the daytime they remain at the sides of the streets, and they only wander into the country at night, in order to find any dead animals which happen to be unburied. Their disposition is meek and peaceable, and they rarely fight with each other. Possibly, all these causes may exempt them from rabies."—(*Larrey, in Mém. de Chir. Militaire, t.* 2, *p.* 226.)

This observation about the exemption of the Egyptian dogs from rabies is very ancient, having been made by Prosper Alpinus.—(*Rer. Ægyptiarum, lib.* 4, *cap.* 8.) According to Barrow, the dogs in the vicinity of the Cape of Good Hope, and in Caffraria, very rarely go mad.—(*Travels into the Interior of Africa.*) Several authors assert that rabies never occurs in South America.—(*Bibl. Raisonnée*, 1750. *Van Swieten, Comment. in Aphor.* 1129. *Portal, &c.*) L. Valentin declares, that it is exceedingly rare in the warm regions of America, but common in the northern part of that continent.—(*Journ. Gén. de Méd. t.* 30.) Dr. Thomas, who resided a good while in the West Indies, never saw nor heard of a case of rabies there (*Practice of Physic*); and Dr. B. Moseley states, that the disorder was not known in those islands down to 1783. On the other hand, the disease sometimes happens in the East Indies, though not with such frequency as at all to justify the doctrine about heat being the cause of its production. The silence of Hippocrates proves, that in his days hydrophobia must have been very rare in Greece; and, as the disorder is not mentioned in the Scriptures, an inference may be made, that it could not be so common in the hot tracts of the globe, inhabited by the Hebrews, as in the temperate climates of Europe and America.

Neither can the sentiment be received as correct, that rabies is more frequent in the north than in the temperate parts of Europe; for De la Fontaine particularly notices how extremely rare it is in Poland.—(*Chir. Méd. Abhandl. Breslau*, 1792.) The disease is reported to be very common in Prussian Lithuania; but mad dogs are seldom or never heard of at Archangel, Tobolsk, or in the country north of St. Petersburg.

In Mr. Meynell's account, which was communicated to him by a physician, it is asserted, that the complaint never arises from hot weather, nor putrid provisions, nor from any cause except the bite; for, however dogs have been confined, however fed, or whatever may have been the heat of the season, the disorder never commenced without a possibility of tracing it to the preceding cause, nor was it ever introduced into the kennel, except by the bite of a mad dog. (See *art. Dog, in Rees's Cyclopædia.*)

Dr. Gillman endeavours to prove, that the disease in dogs is probably excited independently of particular climates, of putrid ailment, of deficiency of water, of want of perspiration, or of the worm under the tongue, to which causes it has been at different times ascribed; and he expresses his belief, that it originates somewhat like typhus in the human subject, and is not always produced by inoculation, or by means of a bite. He thinks, that it may be occasionally brought on by the confinement of dogs, without exercise, in close and filthy kennels; and that the success of Mr. Trevalyan, as related by Dr. Bardsley, in clearing his kennel of the disease, by changing even the pavement, after other means of purification had failed, affords presumptive evidence in favour of the opinion; and, consequently, this author thinks, that the method of quarantine, adopted by Mr. Meynell, and recommended by Dr. Bardsley, on the supposition that the disease originates exclusively from contagion, will not be a sufficient preventive alone: and he infers, from some facts reported by Mr. Daniel, that the poison sometimes lies dormant in dogs, four, five, and six months; and, consequently, that the period of two months is not a sufficient quarantine.—(See *Gillman's Diss. on the Bite of a Rabid Animal.*)

In opposition, however, to some of the sentiments contained in the foregoing passage, it should be known, that Dupuytren, Magendie, and Breschet have purposely kept many dogs for a long time in the most disgusting state of uncleanliness, let them even die in this condition for want of food and water, or even devour each other, yet without exciting rabies.—(*Dict. des Sciences Méd. t.* 47, *p.* 53.) Yet Professor Rossi, of Turin, is said to have produced this, or some similar disease, in cats, by keeping them shut up in a room.—(*Mém. de l'Acad. Imp. de Turin*, 1805 *à* 1808, *p.* 93. *de la Notice des Travaux.*) On the whole, I consider it well proved, that neither long thirst, hunger, eating putrid flesh, nor filth, will occasion the disease in the canine race. At Aleppo, where these animals perish in great numbers from want of food and water, and the heat of the climate, the distemper is said to be unknown. Nor is rabies found to attack dogs and cats with particular frequency during the copulating season, and, therefore, the œstrus veneris cannot be admitted to have any share in its production, as some writers have been disposed to believe.—(See *Dict. des Sciences Méd. t.* 47, *p.* 55.)

Although most writers believe in the reality of a poison, or specific infectious principle, in cases of rabies, the fact has been questioned, or absolutely rejected by others. Bosquillon considered the disease always as the effect of fear, or an impression upon the imagination. This view of the matter is far from being new, and has been ably refuted by many authors, and especially by M. Desault, of Bourdeaux, who remarks, that horses, asses, and mules, *quibus non est intellectus*, had died rabid the very year in which he wrote; and it is observed by Dr. J. Vaughan, that an infant in the cradle is sometimes attacked, while many timorous children escape.

Another notion has partially prevailed, that rabies does not depend upon any virus, but upon the continuance of an irritation in the bitten parts, affecting the whole nervous system.—(*Percival; J. Mease; Girard; &c.*) But this doctrine confounds rabies and tetanus together, and can only apply to the symptomatic non-infectious hydrophobia from an ordinary wound or laceration.

The facts, in proof of the reality of a peculiar infectious principle in cases of rabies, are too numerous to leave any doubt upon the subject. Twenty-three individuals were bit one morning by a female wolf, of whom thirteen died in the course of a few months, besides several cows, which had been injured by the same animal. How could all these unfortunate persons have had similar symptoms, and especially a horror of fluids, had they not been all under the influence of some cause, besides the bites? The patients who died were bit on the naked skin; while in the others, who escaped infection, the bites happened through their clothes, which no doubt intercepted the saliva the vehicle of the virus. In the essay by Le Roux, mention is made of three persons, bit by a rabid wolf near Autun, in July, 1781, and, notwithstanding mercurial frictions, they all died of hydrophobia. Of ten other individuals bit by a wolf, nine died rabid.—(*Rey, Mém. de la Soc. Royale de Méd. p.* 147.) Twenty-four persons were injured in the same manner near Rochelle, and eighteen of them perished.—(*Andry*

Recherches sur la Rage, ed. 3, *p.* 196.) On the 27th January, 1780, fifteen individuals were bit by a mad dog, and attended at Senlis by the commissioners of the French Royal Society of Physic: ten had received the bites on the naked flesh, and five through their clothes. Of the first ten, only five lost their lives, three of them dying of decided rabies between the 27th of February and the 3d of April; and the other two between the 29th of February and the 18th of March. Unless the opinion be adopted, that the disease is caused by an infectious principle, a sort of inoculation, it would be impossible rationally to explain the cause of so many deaths from the bites of rabid animals. If the idea, that rabies originates from fear, or nervous irritation, were true, how could we account for there being such a difference between the usual consequences of the bite of a healthy dog, and those of the bite of one affected with rabies? Healthy dogs are incessantly quarrelling, and biting each other in the streets, yet their wounds are not followed by rabies; and, as a modern author remarks, if hydrophobia were referable to nervous irritation derived from the wounded part, how does it happen, that, among the thousands of wounded after a great battle, hydrophobia is not seen instead of tetanus?—(*Dict. des Sciences Méd. t.* 47, *p.* 61.) But if it were yet possible to entertain a doubt of an infectious principle in hydrophobia, this possibility would be removed by the reflection, that the disease may be communicated to healthy animals by inoculating them with the saliva of certain other rabid animals. In fact, as I have stated, the bites of such animals are in every point of view only an inoculation; and the same remark may be extended to the numerous instances on record, in which the disease arose in the human subject, as a consequence of a rabid dog or cat (not suspected to be in this state at the time) having been played with, fondled, or suffered to lick the naked skin, in which there was at the moment some slight scratch, entirely overlooked.

Many of the ancient writers not only believed in the hydrophobic virus, or infectious principle, but even in its diffusion through the blood, flesh, and secretions in general; and this hypothesis was professed by Boerhaave, Van Swieten, Sauvages, F. Hoffman, &c.; but, in proportion as the humoral pathology lost ground, the foregoing idea was abandoned, and the opinion adopted, that the infection is confined to the saliva, and wounded part, in which it has been inserted.

The tales of some old authors would lead one to think, that hydrophobia may be communicated by eating the flesh of a rabid animal.—(*Fernelius, De Obs. Rer. Caus. et Morb. Epidem. lib.* 2, *cap.* 14; *Schenckius Mangetus, &c.*) But respecting these accounts, it is remarked, that they are not entitled to much confidence; for it is certain that rabies never begins, as is stated with regard to some of the cases in question, a few hours after the application of its cause, and its early stage is never characterized by any fury, or disposition to bite. And, besides, how can such relations be reconciled with the practice of the ancients, who, according to Pliny, employed the liver of the mad dog, or wolf, as a remedy? Palmarius also fed his patients for three days with the dried blood of the rabid animal.—(*Mém. de la Soc. de Méd. p.* 136; *et le No.* 178.) The flesh of a bullock, which had been bit by a mad dog, and afterward died rabid, was sold to the inhabitants of Medola near Mantua, yet none of them were attacked with hydrophobia.—(*Andry, Recherches sur la Rage, &c. p.* 30.) Dr. Le Camus informed Larrey, that he had eaten the flesh of animals, which died rabid, but he suffered no inconvenience from the experiment. And it is stated in the letter of Dr. L. Valentin, that certain negroes in the United States of America had no illness from eating the flesh of pigs which had died of rabies.—(*Journ. Gén. de Méd. t.* 30, *p.* 417.) As for the question, whether the blood is infected? it is generally considered to be settled in the negative, notwithstanding the account given by Lémery of a dog, which was attacked with rabies, as is said, from lapping the blood of a hydrophobic patient, who had been bled.—(*Hist. de l'Acad. Royale des Sciences*, 1707, *p.* 25.) Dupuytren, Breschet, and Magendie were never able to communicate rabies by rubbing wounds with blood taken from mad dogs; and they even several times injected such blood into the veins of other healthy dogs, yet none of these latter animals were attacked with rabies, though they were kept for a sufficient length of time to leave no doubt upon the subject.—(See *Dict. des Sciences Méd. t.* 47, *p.* 63.)

A point of greater practical interest than the former is, whether the drinking of the milk of an animal, labouring under rabies, is attended with any risk of communicating the disease? It is asserted by Tunæus, that a peasant, his wife, children, and several other persons, were seized with hydrophobia, in consequence of drinking the milk of a rabid cow; and that the husband and eldest child were saved by medical treatment; but that the wife and four of the children died. It is farther stated, that three or four months afterward, the maid and a neighbour, who had partaken of the milk of the same cow, also died of hydrophobia.—(*Cons.* 7, *obs.* 33.) In opposition to this account, however, several facts, reported by other writers of greater credit, tend to prove, that hydrophobia cannot be communicated by the milk of a rabid animal.—(*Nova Acta Nat. Cur. vol.* 1, *obs.* 55; *Baudot, in Mém. de la Soc. Royale de Méd. an.* 1782 *et* 83, *t.* 2, *p.* 91.)

The cases reported by F. Hoffman and Chabert, with the view of proving the possibility of infection through the medium of the semen, are of no weight, because, on a critical examination of them, it will be found, that the infection of the women is stated to have taken place very soon after their husbands had been bit, which is quite at variance with the established character of the disease, as it never commences, and of course cannot be propagated in any manner, soon after the receipt of the bite. Besides, these histories are refuted by others of greater accuracy.—(See *Baudot, in Mém. de la Soc. Royale de Méd. an.* 1782, *&c. p.* 92. *Rivallier, vol. cit. p.* 136. 211. *Bouteille, p.* 237. *Boissière, in Journ. Gén. de Méd. t.* 17, *p.* 296.)

Neither can hydrophobia be imparted by the breath, notwithstanding the statements of Cœlius Aurelianus, and some other old writers. A nurse, mentioned by Dr. J. Vaughan, repeatedly kissed a hydrophobic infant, which she had suckled, and exposed herself incessantly to its breath, but without the least ill effects. The fear which has also been entertained, of the disorder being receivable from the application of the patient's perspiration to the skin, is not founded upon any authentic facts.

Does the infectious principle of rabies reside in the salivary secretion, or in the mucus of the trachea and bronchiæ? The common belief is, that, in hydrophobia, the salivary glands are considerably affected. But, it has been remarked by a modern writer, that if these glands exhibit no morbid alteration during the whole course of the disorder; if they are found healthy after death; if the air-passages are the seat of inflammation; if the saliva does not constitute the frothy slaver about the lips; and if such slaver, wherewith the disease may be communicated by inoculation, is derived from the inflamed windpipe and bronchiæ, and consists of mucus converted into a kind of foam by the convulsive manner in which the patient breathes, there is some reason for questioning whether the saliva, strictly so called, undergoes the alteration generally supposed.—(See *Dict. des Sciences Méd. t.* 47, *p.* 66.) However, this writer is not exactly correct, when he describes the frothy secretion about the mouth, as being altogether composed of mucus from the trachea, since a great part of it is unquestionably true saliva and mucus secreted in the fauces and mouth. In the stomachs of dogs, which died rabid, Dr. Gillman constantly observed traces of inflammation, and he once tried to communicate the disease to two rabbits, by inoculating them with matter taken from pustules found in the stomach of a rabid dog; but no infection took place.—(*On the Bite of a Rabid Animal, p.* 32.)

According to professor Rossi of Turin, the nerves "before they grew cold, participated with the saliva in the property of communicating rabies." He asserts, that he once imparted the disease by inserting in a wound a bit of the sciatic nerve, immediately after it had been taken from a living rabid cat.—(See *Mém. de l'Acad. Imp. de Turin, Sciences, Phys. et Mathém. de* 1805 *à* 1808, *part* 93, *de la Notice des Travaux.*)

After all which has been stated concerning the hypothesis of the infectious principle of hydrophobia being more or less diffused through the solids and fluids of a rabid animal, and not being restricted to the saliva, perhaps the safest conclusion to be made is, not to reject the opinion altogether, but to consider it as at present requiring farther proof. And from observa-

tions of what happens in the human subject, the same inferences should not always be drawn, as from experiments on animals, which are liable to be attacked with spontaneous rabies of a decidedly infectious character.—(See *Dict. des Sciences Méd. t.* 47, *p.* 67.)

Although many cases are to be met with in the records of medicine and surgery, tending to convey an idea, that the mere application of the saliva of a rabid animal to the sound entire skin of the human subject, may give rise to hydrophobia, the assertion is contrary to general experience, and liable to a reflection which must overturn the hypothesis; viz. the slightest prick, scratch, abrasion, or broken pimple on the surface of the body, such as would not be likely in many instances to excite notice, may render the application of the saliva to the part a positive inoculation.

Instances are also reported, the tenour of which is to prove, that the hydrophobic virus may take effect through a sound mucous membrane.—(*Palmarius, de Morbis Contag.*; *Portal, Obs. sur la Rage, p.* 131; *Matthieu in Mém. de la Soc. Royale de Méd. p.* 310, *&c.*) But that this does not happen in the human subject is tolerably well proved by the consideration, that formerly a class of men made it their business to suck the wounds caused by the bites of rabid animals; yet none of them contracted hydrophobia from this bold employment.—(*Bosquillon, Mém. de la Soc. d'Emulation, t.* 5, *p.* 1.) The example of the nurse, who repeatedly kissed a child without the least ill effect, while it was dying of rabies, as recorded by Dr. J. Vaughan, has been already noticed. However, if hydrophobia were apparently to arise in any rare instance from the application of the slaver of a rabid animal to the inside of the lips, no positive inference could be drawn from the fact, unless the means were also possessed of ascertaining that there were no slight abrasion about the gums, or within the mouth, previously to such application.

For the hydrophobic virus to take effect, therefore, it is generally, if not always necessary, that the infectious saliva be either applied to an abraded, wounded, or ulcerated surface. In the case of a bite, the teeth are the envenomed weapons, which at once cause the solution of continuity, and deposite the infection in the part. But the mere abrasion of the cuticle, and the application of the infectious saliva to the denuded cutis, will often suffice for the future production of the disease. As the mode of communication, therefore, is a true inoculation, it follows, that the danger must depend very much upon the quantity of infectious matter conveyed into, or applied to the part, the effectual manner in which the saliva is lodged in the flesh, the extent and number of the wounds, and particularly the circumstance of the teeth of the rabid animal having passed through no clothes, by which the saliva might possibly be effectually prevented from entering the wound at all. Hence, bites on the hands and face are well known to be of the most dangerous description, especially those on the face, the hands being sometimes protected with gloves.

From what has been observed, however, it is not to be concluded that the disease always follows, even when the animal which inflicts the bite is decidedly rabid, and some of its saliva is actually applied to the wounded or abraded parts. On the contrary, experience fully proves, that out of the great number of individuals often bit by the same mad dog, and to whom no effectual prophylactic measure is extended, only a greater or less number are afterward attacked with hydrophobia. When this difference in the fate of the individuals cannot be explained by the intervention of their clothes, the thickness of the cuticle at the injured part, the small size and superficial nature of the bite, the ablution of the part, or some other mode in which any actual inoculation may have been rendered ineffectual, it can only be referred to some unknown peculiarities or differences in the constitutions of the several individuals. The latter conjecture seems more probable when the fact is recollected that some animals are more susceptible of rabies than others, and some appear to resist the infection altogether.

Dogs are more susceptible of the infection than the human species. Four men and twelve dogs were bit by the same mad dog, and every one of the dogs died of the disease, while all the four men escaped, though they used no other means of prevention but such as we see every day fail. There is also an instance of twenty persons being bit by the same mad dog, of whom only one had the disease.

Dr. Heysham has defined hydrophobia to be an aversion and horror at liquids, exciting a painful convulsion of the pharynx, and occurring at an indeterminate period after the canine virus has been received into the system. Dr. Cullen places it in the class *neuroses*, and order *spasmi*, and defines it, a loathing and great dread of drinking any liquids, from their creating a painful convulsion of the pharynx, occasioned most commonly by the bite of a mad animal. Others have suggested the following definition as more complete: melancholy, dread of cold air, of any thing shining, and particularly of water; often arising from the bite of a mad animal.—(*Parr's Med. Dict.*) However, the latter definition is, perhaps, equally objectionable, because there is not invariably a dread of shining bodies.—(See *Dr. Powell's Case, p.* 8.) While some authors represent it as a nervous disorder, others, among whom is Boerhaave, consider it as one of an inflammatory nature. In many systems of surgery, hydrophobia is treated of with poisoned wounds, of one species of which it is strictly the effect.

With regard to the symptoms of hydrophobia, they are generally tardy in making their appearance, a considerable, but a very variable, space of time usually elapsing between their commencement and the receipt of the bite. Out of a table of 131 cases, none of the patients became ill before the eleventh day after the bite, and only three before the eighteenth. It is pretended by Pouteau, that one patient was bit by a dog in the morning, and was attacked with hydrophobia at three o'clock in the afternoon. But as this account was communicated to the author a long time after the occurrence, and not by a medical man, it deserves little confidence. Another case, adverted to by Mead, is deprived of all its importance by the same consideration. These examples, as well as another reported by Astruc, in which the patient is said to have had hydrophobia in less than three days, after being wounded on the temples, can at most be regarded only as specimens of symptomatic hydrophobia.—(*Dict. des Sciences Méd. t.* 47, *p.* 74.) There appears to be no determinate period at which the disorder makes its attack after the bite; but it is calculated, that the symptoms most frequently commence between the thirtieth and fortieth days, and that after this time the chances of escape increase. Of fifteen patients, whose cases Trolliet was acquainted with, seven were attacked between the fourteenth and thirtieth days; five between the thirtieth and fortieth; two a little beyond the latter period; and one after fourteen weeks. In May, 1784, seventeen persons were bit by a rabid wolf near Brive, of whom ten were afterward attacked with hydrophobia; viz. one on the fifteenth day after the bite; one on the eighteenth; one on the nineteenth; one on the twenty-eighth; one on the thirtieth; one on the thirty-third; one on the thirty-fifth; one on the forty-fourth; one on the fifty-second; and the last on the sixty-eighth day.—(*Hist. de la Soc. Royale de Méd. p.* 209.) Fothergill and Moseley mention cases in which the disease began four months after the bite; and M. Matthey of Geneva details an instance in which the interval was 117 days.—(*Journ. Gén. t.* 54, *p.* 275.) Haguenot knew of a case in which the interval, between the bite and the commencement of the illness, was five months.—(*Portal, p.* 183.) Dr. J. Vaughan mentions an interval of nine months; Mead of eleven; Galen, Bauhin, and Boissière, of a year; Nourse of nineteen months; and R. Lentilius, of three years.

Dr. Bardsley, of Manchester, has recorded a case in which the most careful inquiries tended to prove, that the patient had never suffered the least injury from any animal, except the bite inflicted twelve years previously to the commencement of the hydrophobia, by a dog apparently mad.—(*Mem. of Liter and Phil Society of Manchester, vol.* 4, *part* 2, *p.* 431.)

A merchant of Montpellier is also stated to have been attacked with hydrophobia ten years after the bite of a rabid dog, which also bit the patient's brother, who died hydrophobic on the fortieth day after the accident.—(See *Dict. des Sciences Méd. t.* 47, *p.* 75.) Here may also be found references to cases, in which the interval is alleged to have been eighteen, twenty, and even thirty years. It is certainly difficult to attach any credit to these very late periods of attack. Dr. J. Hun-

ter considers seventeen months, and Dr. Hamilton nineteen, the longest interval deserving belief.—(*On Hydrophobia, vol.* 1, *p.* 113.) Exposure to the heat of the sun, violent emotions of the mind, and fear, are believed to have considerable influence in accelerating the commencement of the symptoms. That mental alarm is also of itself sometimes capable of bringing on a simple hydrophobia, totally unconnected with infection, is incontestable; a case which has not always been duly discriminated. A most convincing proof of this fact is recorded by Barbantini, in the *Italian Journ. of Physic, Chemistry, &c.* for January and February, 1817. A young man was bit by a dog which he fancied was mad, and on the fifth day he evinced symptoms of hydrophobia, of which he was nearly dying, when the dog which had bit him was shown to him perfectly well, and the intelligence tranquillized him so effectually, that he was quite well four days afterward. Mr. John Hunter is said to have mentioned in his lectures a very similar case, in which he believed the patient would certainly have died, if the dog, which inflicted the bite, had not been found and shown to the patient perfectly well.—(See *Journ. Gén. de Méd. t.* 41, *p.* 215.) It is to the effects of terror that several modern writers are disposed to refer the instances of very late attacks of hydrophobic symptoms after the period when the patients were bitten; though, unless the intellects be changed in the mean time by other causes, it is difficult to conceive, why the alarm should not have the greatest effect earlier, while the impression of the danger is undiminished by time. The idea, that the symptoms begin sooner after the bite of a wolf than that of a dog, is not adopted by a writer who has taken great pains to collect information on the present interesting disorder.—(See *Dict. des Sciences Méd. t.* 47, *p.* 77.)

Cullen has divided the disease into two stages, the hydrophobia *simplex* and *rabiosa*; or the *melancholy* and *raving* stages of some other writers. But as the early stage is frequently unattended with any thing like melancholy, it is best merely to adopt the distinction of the *first* and *second* stages; one comprehending the effects of the disorder previously to the occurrence of a dread or decided aversion of liquids; the other, the subsequent changes. The wound, if treated by common methods, usually heals up at first in a favourable manner. At some indefinite period, and, occasionally, long after the bitten part seems quite well, a slight pain begins to be felt in it, or the neighbouring parts, now and then attended with itching, but generally resembling a rheumatic pain. If the bite took place on the finger, the pain successively extends from the hand to the forearm, arm, and shoulder, without any redness or swelling in these parts, or any increase of suffering from pressure or motion of the limb. In a great number of instances the trapezius muscle, and the neck on the same side as the bite, are the points to which the pain principally shoots. The cicatrix, in the mean while, begins to swell, inflames, and often festers and discharges an ichorous matter. These uneasy, painful sensations recur from time to time, and usually precede any dread of water several days; and they are a just reason for apprehension. Sometimes pains of a more flying, convulsive kind, are felt in various parts of the body. As the disease advances, the patient complains of the pain shooting from the situation of the bite towards the region of the heart. Sometimes, instead of pain, there is rather a feeling of heat, a kind of tingling, or even a sensation of cold extending up to the chest and throat. Occasionally no local symptoms take place; thus Sabatier, in giving account of several cases, remarks it as worthy of notice, that the bitten parts did not become painful previously to the accession of the fatal symptoms: nor did any swelling or festering occur.—(See *Mém. de l'Institut. National, t.* 2, *p.* 249. *&c.*)

Dr. Marcet particularly observed, that the pain follows the course of the nerves, rather than that of the absorbents. In the case which he has related, as well as in one of the cases detailed by Dr. Babington, there was pain in the arm and shoulder, but without any affection of the axillary glands; and in another case (see *Medical Communications, vol.* 2), the pain, occasioned by a bite in the leg, was referred to the hip and loins, without any affection in the inguinal absorbents.—(*Medico-Chir. Trans. vol.* 1, *p.* 156.) Of the accuracy of the foregoing statement, by Dr. Marcet, there is no doubt: the observation, however, in regard to the irritation not affecting the absorbents was long ago anticipated by several authors, who urged the freedom of the lymphatic glands from disease, as an argument that the disorder did not depend upon the absorption of any virus. It is also noticed by others, who inclined to the belief in the absorption of the infectious principle. "Resorptionem virus ope systematis lymphatici fieri verisimillimum videtur; nequo tamen nec vasa lymphatica, nec glandulæ vicinæ stimulo morboso, vel tumore adfici videntur; quod in aliis resorptionibus virulentis fieri solet."—(*Callisen, Syst Chirurgiæ Hodiernæ, vol.* 1, *p.* 595. *Hafniæ*, 1798.)

Pain and heaviness are felt in the head. Sometimes the headache is at first very severe; sometimes but slight; but in the latter case, it often becomes intense, general, and accompanied with a sense of pressure upon the temples. In certain instances, the patient's sleep lasts a good while, though disturbed by dreams; while, in other more frequent examples, he is continually restless. The intellectual functions generally seem increased; the memory stronger; the conception more ready; the imagination more fertile; and the conversation more animated. However, some patients are silent and dejected, and when questions are put to them, the answers are short and peevish. But the greater number are active, lively, and talkative. At the same time the organs of sense betray signs of increased sensibility; and the eyes, which are very open and bright, avoid a strong light. Sometimes the pupil is found to be considerably dilated. Extraordinary pains are felt about the neck, trunk, and limbs. It is not uncommon, also, for the patient to evince great anxiety, or to fall into a state of dull despair and melancholy. These last symptoms, of which great notice is taken by writers, are particularly ascribable to the effect of fear. The disorder of the organs of digestion is sometimes manifested in various ways, though it is far from being so frequent and striking as the affections of the head which precede it. The disorder referred to consists at first in loss of appetite, nausea, vomiting, and afterward constipation, and sometimes colic. In the first stage of the disease the pulse is generally somewhat more frequent and strong than in health, and the countenance appears more animated.

The above symptoms precede the second stage, or that of decided rabies, only by a few days, usually four or six, though sometimes but two or three.—(*Dict. des Sciences Méd. t.* 47, *p.* 78.)

The second stage of hydrophobia commences with the first manifestation of the dread or aversion of liquids. The ungovernable agitation and distressing sense of suffocation excited by the sight of liquids, the attempt to drink, or even the mere idea of drinking, is unquestionably the most remarkable symptom of the disorder. The patient is also frequently attacked with the same kind of commotion and suffering from other causes, such as the least agitation of the air, or exposure to a strong light. Indeed, some patients are so much affected by a blast of wind, that they have been known to endeavour to elude it by walking with their backs towards it (*Hist. de la Soc. Roy. de Méd. p.* 157); while others scream out whenever the window or door of their room is opened.—(*Morgagni, De Sed. et Caus. Morb. Epist.* 8, *No.* 28.)

Dr. Marcet, in relating the case of the patient affected with hydrophobia, observes, that "on our proposing to him to drink, he started up, and recovered his breath by a deep convulsive inspiration; yet he expressed much regret that he could not drink, as he conceived it would give him great relief, his mouth being extremely parched and clammy. On being urged to try, however, he took up a cup of water in one hand, and a tea-spoon in the other. The thought of drinking out of the cup appeared to him intolerable; but he seemed determined to drink with the spoon. With an expression of terror, yet with great resolution, he filled the spoon and proceeded to carry it to his lips; but before it reached his mouth, his courage forsook him, and he was forced to desist. He repeatedly renewed the attempt; but with no more success. His arm became rigid and immoveable whenever he tried to raise it towards his mouth, and he struggled in vain against this spasmodic resistance. At last, shutting his eyes, and with a kind of convulsive effort, he suddenly threw into his mouth a few drops of the fluid, which he actually swallowed. But at the same instant he

jumped up from his chair, and flew to the end of the room panting for breath, and in a state of indescribable terror."—(See *Med. Chir. Trans. vol.* 1, *p.* 158.) Even the splashing or running of any liquid causes a great deal of inconvenience. As the system becomes more and more affected, the patient loses his sleep entirely, and has frequent and violent fits of anxiety and loud screaming from slight causes. The woman, whom Dr. Powell attended, was often attacked in this way, in consequence of so trivial a circumstance as a fly settling on her face. The noise of tea-cups, or the mention of any sort of drink, greatly disturbed her, though she was not at all agitated by the sound of her urine. The currents of air entering her room, whenever the door opened, became very distressing to her, and this more and more so. The pain in her neck became so great that she could scarcely bear it to be touched; but she made use of a looking-glass without the inconvenience which hydrophobic patients usually suffer from the sight of shining bodies. Dr. Powell states, that the paroxysms, which this poor woman suffered, resembled those of hysteria, and increased in duration as the disorder lasted. "She described their commencement to be in the stomach, with a working and fulness there; and that a pricking substance passed up into her throat and choked her; she screamed suddenly, and grasped firmly hold of her attendants, as if voluntarily; and muscular convulsions came on, which were sometimes more, sometimes less, general and violent. The causes from which these paroxysms arose were extremely slight; the passage of a fly near her face, the attempt to swallow a pill, a stream of air, the sight of oil or wine, or any other liquids, even the sound of water, and other such circumstances, were sufficient; she now also complained of inconvenience from light, which was accordingly moderated. The effect of sounds was peculiar; for, though in the subsequent stages their influence became more general, at this period the effect was rather proportionate to the ideas they excited in her mind, than to their violence. Bells, and other strong noises, did not agitate her; but the clatter of earthen ware, the noise of a distant pump, or any thing connected with liquids, produced the paroxysms in all their violence." She could swallow fresh currants with less resistance than any thing else, taking care that they were perfectly dry. Her mind had, till now, been quite calm and composed; and her conversation and behaviour proper, during the intervals of the convulsive attacks. But Dr. Powell was obliged to discontinue the pills of argentum nitratum, in consequence of the sufferings which the attempt to swallow them regularly brought on. Fifteen grains of this substance had been given without any sensible effect. The fits, and the irritability to external objects, increased. The pain shot from the back of the neck round the angles of the jaws, the chin, and throat. At length the paroxysms became more frequent, and, indeed, might be said to come on spontaneously: seven occurred in one hour. She looked pale and exhausted, and a tremor and blueness of her lips and fingers were observable; her pulse became weaker and more rapid, and her scalp so tender that touching it brought on convulsions. She had, latterly, eructations of wind, and spit up some thick viscid saliva. Her urine now came away involuntarily, and she was more and more irritable and uncontrollable. Indeed, she passed two hours in almost constant convulsions; became extremely irritable and impatient of every thing about her: complained of failure of her sight; wished to be bled to death; her words were fewer and interrupted; she struck, and threatened to bite her attendants; had copious eructations of air; discharged an increased quantity of viscid saliva with much convulsive effort; said the affection of her throat and stomach had quite left her; and continued in a general perspiration, with a weak pulse from 140 to 150. She afterward bit some of the attendants, and was therefore confined with a waistcoat. From this period she had lost all control over her mind, and continued for almost four hours in a paroxysm of furious insanity. She now swallowed, with an effort, near half a pint of water: but this was, in a few seconds, vomited up, with some mucus and a greenish fluid. In this violent raving state she continued till within two hours of her death, which took place forty-seven hours after the first marked occurrence of hydrophobia. In the course of the case, she swallowed once or twice a little porter; and also some cinnamon water, with tinct. opii; but they were always vomited up.—(*Dr. Powell's Case of Hydrophobia.*)

It is by no means uncommon for a period to occur, when the horror of liquids undergoes a considerable diminution, or even entirely ceases; the patient quenching his thirst, and this sometimes as well as if he were in perfect health, and so as to raise doubts of the existence of rabies. But after a few hours the dread of fluids comes on again, and with it the convulsive paroxysms, which now become general, violent, and incessant. Dr. Cayol attended a girl, labouring under rabies, who was never affected with any very great dread of liquids, nor an absolute inability to swallow them, though she certainly disliked them, and swallowed them with difficulty.—(*Journ. de Méd. Chir. &c. Avril*, 1811, *p.* 241.) Nay, patients are sometimes seen who can manage to swallow red wine and broth, though their aversion to water is already beyond all control; and other patients can sometimes look at a liquid in a black pot without inconvenience; though any fluid offered to them in a glass will bring on a violent paroxysm of spasm and sense of suffocation. The sight of tears has even been enough to bring on the attack.—(See *Dict. des Sciences Méd. t.* 47, *p.* 79.)

The question has sometimes been entertained whether rabies can ever exist quite unattended throughout its course with a dread of liquids? The possibility of such a case was believed by Mead and others; and an instance is recorded by Mignot, in which the patient died, without having manifested any sign of hydrophobia.—(See *Hist. de la Soc. Roy. de Méd. an.* 1783, 2*me Part*, *p.* 48.) However, it is asserted, that a careful perusal of this case must produce a conviction that the disorder was not rabies; and it is added, that when the histories of this disease on record are critically investigated, none will be found complete, which do not make mention of a more or less decided aversion to fluids. It also appears, from facts referred to, that the dread of liquids does not depend upon the pain which the patient has already suffered from his attempts to drink, as it sometimes occurs before any such attempt has been actually made.—(*Vol. cit. p.* 80.)

An inclination to bite was evinced in the case recorded by Dr. Powell; and also in another reported by Magendie. Yet, this disposition is far from being usual; and it never presented itself in any of the cases which fell under the observation of the author of the article *Rage* in the foregoing publication, or P. Desault, Duchoisel, Dr. J. Vaughan, Sabatier, Dupuytren, &c. And, even when the patient's imagination is so disordered that he cannot help biting, he commonly warns the bystanders to avoid the danger. The frothy slaver, which is voided with considerable and repeated efforts, is a symptom, which is said not to commence before the respiration begins to be convulsive. As the disease advances, there is no remission of the sputation, necessary to clear the throat of this viscous secretion; and, at the approach of death, when it cannot be expelled, it collects in the mouth, and covers the patient's lips.

The symptoms of what is termed cerebral excitement become stronger and more marked in the second stage of the disease. The eyes, the brightness of which is still farther increased, appear, as it were, inflamed; the patient never shuts them again; and, as the daylight and brilliant colours are offensive, he prefers darkness. The hearing becomes very acute, and, as well as the sight, is troubled with hallucinations. The touch is extremely fine; the speech abrupt and rapid; and the conversation energetic, and often expressive of the most touching sentiments.—(*Dict. des Sciences Méd. t.* 47, *p.* 12.)

Dr. Marshall made a very just distinction, between the real convulsions which came on towards the termination of the case in death, and the strong sudden action of the muscles, excited in the course of the disorder by the light, the sight of liquids, and the feel of the air.—(*The Morbid Anatomy of the Brain, &c. p.* 88.) Convulsions and hiccough, in fact, are the symptoms of dissolution.

Delirium is far from being a constant symptom, and only happens the last day of the disorder. Neither is it always without remissions; for the patients affected with it sometimes give rational replies. Every case upon record, where delirium is described as being one

of the first symptoms, or as coming on with the dread of liquids, is set down on good authority, not as true rabies, but a symptomatic hydrophobia attended with mania.

The dread of swallowing liquids, though the most singular symptom of the disease, constitutes but a small part of it. It is true, that none, or very few, recover, who have this symptom, yet they certainly do not die, in consequence of the difficulty of swallowing liquids; for the human body could easily exist double the time, at the end of which the disease usually proves fatal, without food or drink. Besides, the sick can often swallow substances that are nourishing, in a pulpy state, without their lives being thereby at all prolonged. It is not, therefore, the difficulty, or impossibility of swallowing liquids, but the effects of the poison upon the constitution at large, which occasion death.—(*Dr. J. Hunter in Trans. for the Improvement of Med. Knowledge, vol.* 1, *p.* 305.)

The extreme sensibility of the sick to all impressions, appears in the displeasure which they express at even the air blowing upon them; in their dislike to a strong light; in their aversion to new faces, or even the sight of their friends and relations; and in the terror they express at being touched, which throws them into convulsions. In a case related by Magendie, the slightest noise, and even merely touching the patient's hair, excited convulsions of incredible violence. As the disease advances, the mind is more and more filled with dreadful fears and apprehensions.—(*Op. cit. p.* 307.)

In the second stage, the epigastrium, as well as the chest, is the seat of considerable pain; the patient is constipated, but the urine is plentiful and high coloured. Before a certain period, the pulse is generally strong, regular, and a little accelerated; but, towards the end of the case, it becomes small, irregular, feeble, and rapid.—(See *Dict. des Sciences Méd. t.* 47, *p.* 83.)

The duration of life, from the appearance of hydrophobia till death, varies from thirty-six hours to four or five days: the most common period is from two to three days.—(*Dr. J. Hunter, Op. cit. p.* 308.) The event is said to be directly caused by asphyxia, or the cessation of respiration. Of ten persons who were bitten by the same animal, nine died on the second and third day, from the commencement of the horror of fluids, and only one on the fifth day. There is an account of a child at Senlis who lived nine days, but the description of the case, and the circumstance of fourteen worms being found in the intestines, may raise doubts about the nature o. the disease.—(See *Hist. de la Soc. Roy. de Méd. p.* 155. 209.)

Whatever may be the resemblance found between tetanus and hydrophobia, with regard to the rapidity of their course, their causes, and some of their symptoms, the following considerations, as a modern writer observes, will always serve for the discrimination of one disorder from the other: tetanus attacks the muscles of the jaw, which remains motionless, while, in rabies, the jaw is not only moveable, but incessantly moving, in consequence of the efforts unremittingly made by the patient to free his mouth from the thick saliva, with which it is obstructed. In this last disorder, the muscles are alternately contracted and relaxed; but, in tetanus, they always continue rigid. Tetanus is rarely attended with any aversion to liquids, and the patient may be kept for a long time in a bath without inconvenience; and the paroxysms are neither excited nor increased by a vivid light, a noise, the patient's being touched, or the sight of water, or shining surfaces. In addition to these differences, it is to be remembered that tetanus is most frequent in warm climates, and that it mostly comes on a few days after the receipt of a local injury, and may occur as a complication of any kind of wound, even that which is made in a surgical operation.—(See *Dict. des Sciences Méd. t.* 47, *p.* 68.)

On the subject of prognosis, with respect to the bite inflicted by a rabid animal, and its effects, as evinced in the decided form of rabies, there are several things worthy of attention. According to some writers, small wounds are not less dangerous than others, and an attempt is made to account for the fact, by the more copious hemorrhage from larger wounds, and the frequent neglect of less injuries. Perhaps another reason is, that the virus is more likely to be confined in a wound with a small orifice, than in one which is ample, and admits of being more effectually washed. The more numerous the wounds are, the greater is the risk. If it be inquired, what is the average number of persons attacked with rabies, out of a given number who have received bites?—the question can only be answered by referring to the extremes. Thus, Dr. J. Vaughan speaks of between twenty and thirty individuals, bit by a mad dog, of whom only one was afterward attacked with rabies; and Dr. J. Hunter tells us of an instance, in which, out of twenty-one persons bit, only one became affected.—(See also *Fothergill in Med. Obs. and Inq. vol.* 5, *p.* 195.) On the other hand, out of fifteen persons, bit by a mad dog, and taken care of at Senlis, three at least were seized with the disorder (*Hist. de la Soc. Roy. de Méd. p.* 130.) Of seventeen others, bit by a wolf, ten were attacked (*ib. p.* 130), and of twenty-three, bit by a she-wolf, thirteen died of rabies.—(*L. F. Trolliet, Nouveau Traité de la Rage, &c. Obs. Chirurg. &c. No.* 25.)

Two important facts should always be recollected, viz. the disease may often be prevented; it can hardly ever be cured. Experience has fully proved, that when hydrophobia once begins, it generally pursues its dreadful course to a fatal termination, the records of medicine furnishing very few unequivocal and well authenticated cases to the contrary. Hence, the imperious necessity of using every possible means for the prevention of the disorder.

Probably, however, many things which possess the character of being preventive of hydrophobia, have no real claim to such reputation. I would extend this observation to all internal medicines, mercurial frictions, and plunging the patient for a considerable time under water.

The instances, in which a prevention is inferred to have taken place by different writers, in consequence of such means, may all be very rationally ascribed to other circumstances. Facts already cited sufficiently prove, that out of the great number of persons, frequently bitten by the same dog, only a limited proportion is commonly affected. The hydrophobic poison is known to reside in the saliva of the animal; consequently, the chance of being affected must greatly depend upon the quantity of this fluid which is insinuated into the wound; and, if the teeth of the animal should have previously pierced a thick boot, or other clothing, before entering the skin, the danger must obviously be much diminished. Many patients wash and suck the wound, immediately after its occurrence, and thus, no doubt, very often get rid of the poison. Even when it is lodged in the wound, it may not be directly absorbed, but be thrown off with the discharge. All prudent patients submit to excision of the bitten part. Now, under each of the above circumstances, escapes have frequently occurred, while internal medicines, half drowning, or salivating the patients, had also not been neglected, so that all the efficacy of preventives has too often been most unjustly ascribed to means, which probably never yet had, and never will have, any beneficial effect whatever. What confirms the truth of the preceding statement is these facts: that persons bitten by the same animal have sometimes been treated exactly on the same plan; some of them escaped the disease; others had it, and, of course, perished: on other occasions, some of the patients, bitten by the same animal, have been treated in a particular way, and have escaped hydrophobia; while others bitten at the same time by the animal, also never had any constitutional effects, although they took no medicines, nor followed any other particular plan.

If to these reflections be added the consideration, that it is frequently doubtful, whether the bite has actually been inflicted by a truly rabid animal, and that the mental alarm will sometimes bring on a symptomatic hydrophobia, it is easily conceivable, how mistaken a person may be, who believes that he has prevented the disorder, and how unmerited is the reputation of the means which he has employed for the purpose.

The bite of a naturally ferocious beast has often been thought to be attended with more risk, than that of an animal naturally tame; and hence, the bite of a wolf is said to be more frequently followed by rabies than that of a dog. This proposition is admitted to be true; but the explanation is erroneous. The true reason of the difference is, that a wolf usually seizes the face, and inflicts a deeper bite; while a dog only snaps as he runs along, and mostly bites through the

clothes.—(See *Dict des Sciences Méd. t.* 47, *p.* 88.) The bite of a rabid animal may be rendered much more dangerous by being situated near a part, or an organ, which increases the difficulty or risk of adopting an effectual mode of removing the whole of the flesh in which the virus may be lodged. Thus, bites near the large arteries, the eyes, the joints, &c. are of a more serious description than others. Dr. J. Hunter rated the hazard in some degree by the vascularity of the bitten parts. The prognosis will always be more unfavourable, when no proper measures have been applied to the bite soon after its infliction, and perhaps the risk may be increased by certain causes not having been duly avoided, which, as already stated, are thought to have a tendency to accelerate the attack of rabies. The exact time after a bite, when the prevention of rabies is no longer practicable, is quite an undetermined point; but every fact, known upon the subject, evinces, in an urgent manner, the necessity of adopting preservative measures without the least delay.

In almost all the dissections of patients, who have died of rabies, certain indications of inflammation have been perceptible, more frequently in some part of the space between the pharynx and the cardiac orifice of the stomach, in the stomach itself, in the lungs, the choroid plexus, and membranes of the brain.—(See *Med. Repository, vol.* 3, *p.* 51.) M. Trolliet opened, with the greatest care, six bodies of persons destroyed by this disease. The mouth and fauces in each subject were first examined, and found of a pale grayish colour, scarcely lubricated with mucus, and quite free from all frothy matter. All the salivary glands seemed perfectly healthy. When the larynx, trachea, and bronchiæ were opened, they appeared to have been the seat of inflammation, the traces of which were the most marked low down, where the mucous membrane was of the colour of wine-lees. In four of the bodies, frothy mucus was perceived in the bronchiæ, larynx, and trachea. Trolliet infers from these appearances, that the frothy matter, seen about the mouth and lips of patients affected with rabies, is secreted by the inflamed mucous membrane of the bronchiæ, and that it is this secretion, and not the real saliva, which contains the hydrophobic poison.—(*Nouveau Traité de la Rage, &c.*) In giving an account of a dissection, Faure also long ago remarked, that the frothy matter was only met with in the air-passages, that the salivary organs were unaffected, and that the saliva itself did not contribute to the formation of the thick slaver, which appeared to have issued from the chest.—(*Hist. de la Soc. Roy. de Méd. ann.* 1783, *p.* 39.) From the preceding observations, and those of Mignot de Genety (*Vol. cit. p.* 54), Morgagni (*De Sedib. et Caus. Morb. Epist.* 8, *art.* 20, 25, 30), Darlue (*Journ. de Med. de Vandermonde, t.* 4, *p.* 270), B. Rush, and Dupsey (*Obs. Inédites, No.* 138.), it would appear:

1. That the mouth, strictly so called, and the salivary glands are without any alteration.

2. The mucous membrane of the air-passages is affected with inflammation, which in its highest degree extends from the division of the bronchiæ to the pharynx. When the inflammation is of less extent, the pharynx appears sound; and when yet more limited, it is usually not to be traced in the larynx. The point where it seems to commence and is most strongly marked, is at the lower part of the trachea, or in the bronchiæ. Lastly, when none of these parts are found inflamed, the lungs themselves present vestiges of inflammation.

With respect to the theory of Trolliet, wherein the hydrophobic poison is said to be contained in the mucous secretion voided from the lungs, and to be the product of inflammation of the membrane of the bronchiæ, and not derived from the salivary glands, the question requires the confirmation of experiment; for, though the salivary glands are not the seat of pain, swelling, &c., it by no means follows, that their secreting process may not have been subject to some peculiar modification, on which the production of the hydrophobic virus depended. Thus, severe and obstinate ptyalisms often occur, and yet there is no manifest change in the state of the salivary glands. According to Van Swieten and Mead, there are sometimes no morbid appearances either in the head, fauces, chest, or stomach.—(*Comment. in Boerh. t.* 3, *p.* 562.)

The dissections of two rabid sheep have been lately published in France and it is particularly noticed, that in these animals the lungs were sound (*Magendie's Journ. t.* 8, *p.* 330, *&c.*); a fact that is very repugnant to the hypothesis adopted by Trolliet.

In three cases out of six, the lungs were found emphysematous, that is to say, their interlobular substance was distended with air, and the pleura pulmonalis raised into a great number of transparent vesicles on the surface of the lungs. In a fourth instance, the emphysema was not observed in the lungs themselves, but in the cellular substance between the two layers of the mediastinum, and under the muscles of the neck. Morgagni also noticed vesicles of air on the surface of the lungs of a person who died of hydrophobia.—(*De Sed. et Caus. Morb. Epist.* 8, *art.* 30.) M. Trolliet presumes that this emphysema is occasioned by the rupture of one of the air-cells in the convulsive efforts of respiration, as sometimes happens when a foreign body is lodged in the larynx.—(See *Cases by Louis and Lescure in Mém. de l'Acad. de Chir. t.* 4, *p.* 538; *t.* 5, *p.* 527.)

The lungs were of a deep-red colour in all the six subjects dissected by Trolliet, and they were observed to be gorged with blood in cases reported by numerous writers; as Bonet (See *Van Swieten, t.* 3, § 1140); Boerhaave (*Op. Omn. p.* 215); Morgagni (*De Sedibus et Caus. Morb. Ep.* 8, *art.* 23, *&c.*); Mead, Darlue (*Recueil Période. &c. t.* 3 *and* 4); Faure (*Hist. de la Soc. Roy. de Méd. p.* 33); De la Caze (*ib. p.* 69); Portal, Oldknow, Ballingall (*Edinb. Med. and Surg. Journ.*); Marshall (*Morbid Anatomy of the Brain, &c. p.* 69); Gorey (*Journ. de Méd. Chir. t.* 13, *p.* 83); Ferriar (*Med. Hist. and Reflections, &c.*) "Pulmones in quinque nigri ex toto aut magnâ parte (says Morgagni), in quatuor magnâ item ex parte sanguine pleni." In a case examined by M. Ribes, the larynx, trachea, and bronchiæ, besides presenting traces of inflammation, were every where lined with a thick white frothy mucus.—(*Magendie's Journ. t.* 8, *p.* 232.) With respect to the state of the organs of the circulation, in three of the cases dissected by Trolliet, a good deal of air escaped from the heart and aorta. Morgagni is supposed to be the only other writer who has noticed a similar occurrence (*Epist.* 8, *No.* 30), and who also in another case saw air escape from beneath the dura mater.—(*Ib. No.* 23.) In two of Trolliet's cases, some gelatinous clots were found in the heart and large vessels; but the great mass of blood was black, and very fluid in the heart, arteries, and veins, as in subjects who have died of asphyxia. In all the six cases, traces of inflammation were noticed in the brain or its membranes. The sinuses were filled with a dark-coloured fluid blood; and the pia mater was much injected, and of a brownish hue. The same appearances were found upon the cerebellum, and the vessels on the investment of the medulla spinalis were considerably enlarged. The surface of the cerebrum was also studded with scarlet spots, which appeared to arise from blood effused from the small vessels of the pia mater into its cellular substance. In two subjects, blood was extravasated towards the base of the brain in larger quantity. The plexus choroides was gorged with blood, and of a brown colour. Besides these and other changes, Trolliet remarked in two of the cases a thickening of the pia mater. The substance of the brain was generally softer than usual; but the fluid in the lateral ventricles was not in large quantity, though in two cases it had a bloody tinge. The late Dr. Marshall believed that in rabies the brain was the part principally affected.—(*Op. cit. p.* 145.)

Hufeland conjectured that in hydrophobia the medulla spinalis is the part originally affected, whence the effects of the disease are propagated to the nerves of the trunk.—(*Bibl. Méd. t.* 55, *p.* 395, *&c.*) Dr. R. Read believed that an alteration of the spinal marrow was essentially concerned in the disease.—(*On the Nature, &c. of Tetanus and Hydrophobia*, 8vo. *Dublin*, 1817.) A case was also published by M. Matthey of Geneva, in which a quantity of serum was found within the spinal canal.—(*Journ. Gén. de Méd. t.* 54, *p.* 279.) See on this subject some observations by Dr. Abercrombie.—(*Edinb. Med and Surg. Journ. vol* 14, *p.* 66.) In one instance, dissected by M. Ribes, the vessels of the pia mater, brain, and medulla spinalis, were gorged with dark blood, but without any appearance of inflammation.—(See *Magendie's Journ. t.* 8, *p.* 232.)

According to Trolliet, the traces of inflammation

in the digestive organs are not so constant as in the lungs and brain. In none of the six cases dissected by him was there any appearance of inflammation in the pharynx, though some parts of the alimentary canal were affected in this manner. The cases recorded, however, in which the digestive organs presented considerable morbid appearances, are very numerous. Thus Joseph de Aromatarius, Darlue (*Recueil Périod. t.* 3, *p.* 189, *et t.* 4, *p.* 270), Sauvages (*p.* 107), Professor Rossi, M. Gorci (*Journ. de Méd. Chir. &c. t.* 13), and Dr. Powell (*Case of Hydrophobia*), found inflammation either in the pharynx, or œsophagus, or both these tubes. Dr. Powell's words are, "the œsophagus was rather redder than natural, and covered with a thin layer of coagulable lymph." A similar coat of lymph was also found by Oldknow (*Edinb. Med. and Surg. Journ. vol.* 5, *p.* 280), Ballingall (*Op. cit. vol.* 11, *p.* 76), Dr. Ferriar (*Med. Hist. &c. vol.* 3, *p.* 27). In dogs, Dr. Gillman found the pharynx and œsophagus in a state of inflammation.—(*On the Bite of a Rabid Animal, p.* 13. 23. 26. 44.) M. Ribes found the pharynx and soft palate slightly inflamed. It is conjectured, that, in many of these instances, the inflammation extended to the œsophagus from the trachea and bronchiæ.—(*Dict. des Sciences Méd. t.* 47, *p.* 98.) Inflammation of the mucous membrane of the stomach and small intestines has likewise been very generally noticed, as may be seen by referring to the accounts published by Morgagni, Powell, Oldknow, Ferriar, Ballingall, Marshall, &c. In dogs, the same fact was remarked by Dr. Gillman (*p.* 13. 31. 44); sometimes, however, according to this last author, no vestiges of inflammation, nor any other morbid appearances, are discoverable in the examination of animals that have died of rabies.—(*P.* 83.) Dupuytren is stated to have found the mucous membrane of the stomach and bowels inflamed in several places, and even almost gangrenous.—(*Dict. des Sciences Méd. t.* 47, *p.* 98.) By M. Ribes, the gall-bladder was found empty; the mucous coat of the stomach, jejunum, and ileum inflamed: and these organs much contracted.—(See *Magendie's Journ. t.* 8, *p.* 233.)

From recent investigations, made at the veterinary school at Alfort, by Professor Dupuy, the following are the usual morbid appearances noticed in the dissection of dogs, horses, cows, and sheep, destroyed by rabies. 1. The lungs and brain universally gorged with blood. 2. Greater or less marks of inflammation in the mucous membrane of the bronchiæ, trachea, larynx, throat, œsophagus, stomach, and frequently even in that of the bowels, vagina, uterus, and bladder. Yet, in two dissections more recently recorded, no particular changes were discoverable in the pharynx and œsophagus.—(*Magendie's Journ. t.* 8, *p.* 331, 332.) 3. The air passages filled with frothy mucus. 4. A collection of serum in the ventricles of the brain, and sometimes even between the membranes covering the spinal marrow. 5. An unusual redness of the investment of the pneumogastric and trisplanchnic nerves.—(See *Dict. des Sciences Méd. t.* 47, *p.* 99.)

Happily, surgery possesses one tolerably certain means of preventing hydrophobia, when it is practised in time, and in a complete manner. Every reader will know, that the excision of the bitten parts is the operation to which I allude. Indeed, as hydrophobia is often several months before it begins, the wounded parts should, perhaps, always be cut out, even though they are healed, and some weeks have elapsed since the accident, provided no symptoms of hydrophobia have actually commenced. The operation should be done completely; for a timorous surgeon, afraid of cutting deeply enough, or of removing a sufficient quantity of the surrounding flesh, would be a most dangerous one for the patient. All hopes of life depend on the prevention of the disorder; for, in the present state of medical knowledge, none can rest upon the efficacy of any plan, except the extirpation of the part. For this purpose, caustics have sometimes been employed. However, as their action can never be regulated with the same precision as that of the knife, and, consequently, they may not destroy the flesh to a sufficient depth, excision should always be preferred. The latter method is also the safest for another important reason, viz. the part, and poison lodged in it, are removed from the body at once; but, when the cautery or caustic is used, the slough must remain a certain time undetached. Some surgeons are not content with cutting out the part, but, after the operation, fill the wound with the liquor ammoniæ, or cauterize its surface, for the sake of greater security. How late excision may be done with any prospect of utility, I am not prepared to say; but there are practitioners who deem excision right even when heat, irritation, or inflammation is observed in the bitten part.—(See *Med. Repository, vol.* 3, *p.* 54.)

Cases present themselves in which it is even preferable to amputate the limb than attempt to extirpate, either with the knife or cautery, the whole of the bitten parts; an endeavour which could not be accomplished with any degree of certainty. Thus, as Delpech observes, when the hand or foot has been deeply bitten in several places, it is obvious that it would be impossible to make caustic (or the cautery) certainly reach every part which the saliva of the rabid animal may have touched. Besides, the mischief resulting both from the injury and the other proceedings together, might be such as to afford no prospect of saving the limb, or at least of preserving it in a useful state.—(See *Précis Elém. des Mal. Chir. t.* 2, *p.* 133.) I have known of one or two cases in which the patients lost their lives in consequence of the excision or destruction of the bitten parts not having been attempted, on account of the surgeon's reluctance to cut tendons, or wound a large artery, as one of those at the wrist. In such cases, however, the fear of rendering a muscle useless, or of wounding an artery, is no justification of leaving the patient exposed to a danger so surely fatal as that of the hydrophobic virus, if it once affect the constitution. The artery should be exposed for a sufficient length, and secured with two ligatures, when the requisite extirpation of the parts between them may be safely performed.

When once the hydrophobic symptoms have commenced, there is little or no hope of saving the patient, the disease having almost invariably baffled every plan of treatment which the united talents of numerous medical generations have suggested. All the most powerful medicines of every class have been tried again and again; mercury, opium, musk, camphor, arsenic, the nitrate of silver, cantharides, belladonna, ammonia, plunging the patient in the sea, bleeding, &c. &c.

The inefficacy of opium is now generally acknowledged: in the space of fourteen hours, Dr. J. Vaughan gave one patient fifty-seven grains of opium, and also half an ounce of laudanum in a glyster, but the fatal termination of the disease was not prevented. Dr. Babington even prescribed the enormous quantity of 180 grains in eleven hours, without the least amendment, or even any narcotic effect.—(*Med. Records and Researches, p.* 121.) On the very first day that rabies decidedly showed itself in a man, who had been bit by a mad dog, Dupuytren injected into the vena saphena, by means of Anel's syringe, two grains of the extract of opium dissolved in distilled water, and as a degree of calm appeared to be the result, four grains more were thrown into the cephalic vein. The patient remained perfectly tranquil three hours longer; but the symptoms afterward recurred with increased violence. The next morning, about six or eight grains more were dissolved and thrown into the circulation; but all was in vain, as the patient died in three-quarters of an hour after the last injection.—(See *Dict. des Sciences Méd. t.* 47, *p.* 131.) By Dr. Brandreth, a solution of the acetate of morphine has been more recently tried, without success.—(See *Edinb. Med. Journ. No. LXXXII p.* 76.)

As for belladonna, its employment for the prevention and cure of hydrophobia is very ancient, its external use for this purpose having been mentioned by Pliny, and its internal exhibition, with the same view, by Theod Turquetus, in a posthumous work published in 1696.—(See *Praxeos Medicæ Syntagma, &c.*) In 1763, belladonna was recommended by Schmidt as a remedy for hydrophobia, and in 1779 by J. H. Munch.—(See *Richter's Chir. Bibl.*) It has so frequently failed, that, in this country, very little confidence is now put in it; but in Italy it is still employed, and some cases, published by Brera, where it was exhibited in very powerful doses, in conjunction with the warm bath, and mercurial friction, tend to show, that it will sometimes arrest the disease in its incipient state.—(*Mem. Soc. Ital. Scienza Modena, t.* 17.)

A few years ago, the public hope was raised by the accounts given of hydro-chlorine, or oxymuriatic acid

Wendelstadt even published the story of an Englishman, who allowed himself to be bit several times by a mad dog, and then saved himself by washing the bites with this acid. And, still more recently, Brugnatelli, in the Italian Journ. of Physic, Chemistry, &c. (*t.* 9, *p.* 324), has published some observations tending to prove its efficacy. The bites are washed with it, and then covered with charpie wet with it. And, when the symptoms commence, if it cannot be swallowed in a fluid form, Brugnatelli gives bread pills imbued with it. For a child eight years old, the dose is ℈ij. four or five times a day, but gradually increased. According to Orfila, hydro-chlorine was long since recommended by Cluzel as an internal remedy for hydrophobia.—(*Secours à donner aux Personnes empoisonnées, &c.* 8vo. *Paris*, 1818, *p.* 153.) With regard to Brugnatelli's cases, they are said to be so destitute of precision, that no inference can be drawn from them.—(*Dict. des Sciences Méd. t.* 47, *p.* 119.) In order to give hydrochlorine a fair trial, it was used internally and externally on seven patients in the Hôtel Dieu at Lyons, in 1817. The bites were washed and bathed with it, and some of them also cauterized; and each patient took daily a drachm of the acid, made into an agreeable sweetened drink. All these unfortunate individuals afterward died of rabies, though the treatment was begun the day after the receipt of the wounds.—(*L. F. Trollier, Nouveau Traité de la Rage, &c.*) The excision of the bites 70 hours after their infliction, and washing the wound with oxymuriatic acid, did not, in Dr. Johnson's case, prevent the disease.—(See *Edinb. Med. and Surg. Journ. vol.* 15, *p.* 212.) In America, the plant scutellaria laterifolia has been greatly extolled as a certain specific for hydrophobia.—(See *a History of Scutellaria Laterifolia, as a remedy for preventing and curing Hydrophobia, by Lyman Spalding, M. D. New-York*, 1819.) And M. Marochetti, of Moscow, has described a new treatment, which consists in giving large doses of genista tinctoria, or butcher's broom, and pricking with a lancet, and then cauterizing with a hot needle some little pustules said by him to form at the orifices of the sub-maxillary glands, between the third and ninth days from the period of the bite, the mouth being afterward well washed out with the decoct. genistæ. M. Magendie, West, and various English practitioners, however, have not been able to discern these sublingual pustules, possibly in consequence of their having looked for them too late, that is, after the accession of the constitutional disorder; for it appears that M. Magistel, of Saintes, has noticed such pustules in several patients. Some arose on the 6th day, others later, and the latest on the 32d day. Of ten persons bitten, whom M. Magistel attended, five died, notwithstanding the strict adoption of Marochetti's treatment.—(See *Journ. Gén. de Méd.*) M. Villermé also observed a transparent pustule under the left side of the tongue, in the case of a female, on the eighth day from the bite.—(*Revue Méd. Anderson's Quarterly Journ. vol.* 1, *p.* 124.) In relation to this part of the subject, it merits notice, that the vesicles were particularly sought for in two rabid sheep at the veterinary School of Alfort, but could not be detected.—(*Magendie's Journ. t.* 8, *p.* 328.) The prussic or hydrocyanic acid has likewise been proposed, on account of its reputed anti-spasmodic properties; but some experiments made with it on dogs by Dupuytren, Magendie, and Breschet, furnish no results in favour of its being likely to prove useful in the present disorder.—(See *Dict. des Sciences Méd. t.* 47, *p.* 132.) Indeed, the following statement, if correct, leaves little hope that any effectual medicine for hydrophobia will ever be discovered. "The most active substances, the most powerful narcotics (says M. Magendie), have no effect upon man or animals attacked with rabies. I do not merely speak of substances introduced into the stomach, and the operation of which may be prevented or diminished by so many circumstances: I speak of substances injected into the veins, and the effects of which must be equally prompt and energetic. For instance, I have several times introduced into the veins of rabid dogs very strong doses of opium (10 grains), without producing the least narcotic effect, while a single grain of the watery extract, injected into the veins of a healthy dog, immediately makes him fall asleep, and often continue so eight or ten hours. The same phenomena are remarked in our own species. M. Dupuytren and I injected into the radial vein of a young man labouring under hydrophobia, about eight grains of the gummy extract of opium, without any apparent result. We have also seen mad dogs bear the introduction of prussic acid into their veins, without an instant's remission in the progress of their disorder."—(*Journ. de Physiologie, t.* 1, *p.* 41.) M. Magendie frequently noticed in his experiments, that an artificial aqueous plethora manifestly enfeebles all the functions of the animals subjected to it, and especially those of the nervous system. Hence, he was led to think that some benefit might arise from it in a case where the activity of the nervous system is at its greatest height. His idea received encouragement also from considering that, in hydrophobia, the patient takes no drink to replace the fluid separated from the circulation by the cutaneous and pulmonary perspiration, and that, after venesection, the blood seems as if it hardly contained any serum. The experiment was first tried on a rabid dog, from which about a pound of blood was drawn, and then 60 oz. of water injected into the left jugular vein, about 10 or 12 oz. of blood, mixed with water, however, being purposely allowed to flow out during the latter part of the operation. The animal, which had previously been quite furious, now became tranquil; but five hours afterward it was attacked with difficulty of breathing, which ended fatally in about an hour.—(*Vol. cit. p.* 44, *&c.*) On the 15th of October, 1823, M. Magendie injected a Paris pint of water, heated to 30 deg. Reaumur, into the veins of a man's arm, who was labouring under hydrophobia in an advanced and violent form. Directly after the operation, the patient, from being furious, became tranquil; the pulse fell from 150 to 120, then to 100, and in twenty minutes to 80. The convulsive motion ceased, and the patient drank a glass of water without any difficulty. Notwithstanding a hemorrhage from the bowels, he continued to improve till the 5th day, when he was seized with acute pains, and swelling of the wrists, knees, and elbows, and threatened with an extensive abscess of the leg, the consequence of the lodgment in the foot of two pieces of lancets, broken in the attempt to bleed him, while he was suffering violent paroxysms in a previous stage of the disorder. Despondency and mental agitation again came on, and he died early on the 9th day from the experiment. On dissection, the swelled joints were found filled with pus; the mucous membrane of a part of the small intestines reddened by the expansion of veins; several small ulcerations in the ileum where it joins the cœcum; the blood in a decidedly putrefied state; the heart and large vessels distended with gas; air under the peritoneal coat of the stomach and intestines; posterior part of the lungs a little swelled; trachea sound, but the bronchiæ red. Magendie considers this case on the whole very favourable to the practice; and when it is reflected, that the patient underwent, directly after the experiment, a great and sudden change for the better, lived eight days after the injection, and then possibly died rather from other accidental complaints, it must be acknowledged, that the method seemed well deserving of farther trials. I would also particularly recommend its adoption in an earlier stage, and while the patient is less reduced, than the one on whom the experiment was made and failed, in one of the borough hospitals. By Dr. Rossi, of Turin, the trial of galvanism was suggested (*Alibert Nouveaux Elémens de Thérapeutique, t.* 2, *p.* 436, *ed.* 4); yet the only fact brought forward, as an encouragement to persevere with the last means, appears to a modern author, from its symptoms and progress, not to have been a case of true rabies.—(*Dict. cit. t.* 47, *p.* 126.) The rapid and powerful effects of the bite of a viper on the whole system, and perhaps the idea that the operation of this animal's venom might counteract that of the hydrophobic virus, led some experimenters to try what would be the result of subjecting patients, affected with rabies, to the bite of that kind of snake. The project, however, was attended with no success. Three cases of this description were communicated to the Royal Society of Medicine (*Hist. p.* 201); two additional ones were recorded by Dr. Gilibert, physician to the Hôtel Dieu at Lyons (*Advers. Méd. Pract. p.* 257); and Viricel, surgeon of the same hospital, repeated the experiment on a child, which yet fell a victim to hydrophobia. Other trials are also said to have been made in France and Germany with no better success. Dr. de Mathiis, in the year 1783, let a viper bite a rabid dog on the throat. The dog's head

was attacked with considerable swelling, the hydrophobia ceased, and, according to some accounts, the animal perfectly recovered, but, according to other statements, though it drank freely as soon as its head had swelled, it only survived the experiment a few hours.—(See *Dict. des Sciences Méd. t. 47, p.* 126.)

Some facts, which occurred a few years ago in the East Indies, tended for a time to raise an expectation, that a copious abstraction of blood might be the means of preserving patients actually attacked with this fatal disorder. Mr. Tymon, assistant surgeon of the 22d light dragoons, tried successfully the method of taking away at once an immense quantity of blood from the patient. "I began by bleeding him (says Mr. Tymon) *until scarcely a pulsation could be felt in either arm.*" Opium was afterward given, and the patient salivated with mercury.— (See *Madras Gazette of Nov.* 23, 1811.)

Although in the observations, annexed to this case by Dr. Berry, there are some circumstances which render it probable, that the case was really hydrophobia: yet, as the successful termination of it is an event so extraordinary, I much regret that some desirable information is omitted. For instance, we have no account of any pain or changes in the bitten part or limb, at the first coming on of the indisposition. The early constitutional symptoms are not described, and the violent spasms, screaming, &c., are the first things mentioned. Some particulars of the dog would also have been interesting.

Such information, indeed, becomes still more essential, when we find it stated that another man, Serjeant Jackson, was also bitten by the same dog, and had hydrophobia *in a mild form*, from which he recovered under the use of mercury, blisters to the head, and cathartic injections, without any recourse to bleeding at all. This last case is even more contrary than the former to what general experience teaches; because mercury, blisters, and injections have been tried a thousand times unavailingly; while, perhaps, bloodletting, *in the manner practised by Mr. Tymon*, is a new treatment. Dr. Shoolbred, of Calcutta, published a second case of hydrophobia cured by bleeding ad deliquium animi, and afterward exhibiting calomel and opium. The patient being threatened with a relapse, was largely bled again. The whole of the success is imputed by Dr. Schoolbred to the venesection. But this gentleman is not so sanguine as to believe that bleeding will cure every case of hydrophobia. It is probable that there is a period, beyond which its curative effect cannot extend, and, therefore, it is upon the first appearance of unequivocal symptoms of the disease, that he thinks copious bleeding affords a prospect of success, while the delay of only a few hours may prove fatal. He observes, that the medical profession, taught by numerous disappointments, admit very cautiously the claims of any new practice to general adoption. If several patients in hydrophobia, therefore, should happen to be bled in an advanced stage of the disease, and die (as they inevitably would do, whether they had been bled or not), such cases would be quoted against the new practice, as failures. But Dr. Shoolbred argues, that numerous failures in an advanced stage of the disease, can form no just ground for the rejection of a remedy which has effected a cure in an earlier stage. He insists upon the necessity of making a large orifice in the vein, so as to evacuate the blood quickly, which must be allowed to flow, without regard to quantity, ad deliquium animi.

Dr. Shoolbred was well aware that bleeding had often been tried in hydrophobia; but, says he, owing probably to the evacuation not having been pushed far enough, when used in the early stage of the disease, or to the period for its beneficial employment having elapsed, the cases in which it was tried afforded little or no encouragement to the continuance of the practice.

Since the preceding cases, the effect of bleeding has had the fairest trials made of it, and some of the reports are in favour of its occasional utility.—(See *Particulars of the successful Treatment of a Case of Hydrophobia, by R. Wynne*, 8vo. *Shrewsbury*, 1813; *also Edmonstone in Lond. Med. Repository, vol.* 3 *p.* 93.) In almost every instance, however, it fails in hindering the usual melancholy event.—(See *Kerrison's Case and Obs. in Med. Repository, vol.* 2. *p*, 197.) This unpleasant truth I think, receives confirmation from the fact, that the practice is far from being new.

Dr. Mead, who was very confident that he had found an infallible preventive of the disease *in a little liverwort and black pepper*, aided by bleeding and cold bathing before the commencement of the course of medicine, says, "As to all other ways of curing the hydrophobia, I own I have not been so happy as to find any success from the many I have tried. Bathing at this time is ineffectual. *I have taken away large quantities of blood;* have given opiates, volatile salts, &c. All has been in vain, *because too late.*" Notwithstanding his disappointment, he concludes, "If any relief could be expected in this desperate state, I think it would be *from bleeding, even ad animi deliquium*," *&c.*

The doctrines of Boerhaave also led him and his pupils to recommend and practise bleeding in hydrophobia. "The distemper (says he) is to be treated as one highly inflammatory, upon the first appearance of the signs which denote its invasion, by *blood-letting from a large orifice, continued till the patient faints away;* and soon after by enemata of warm water and vinegar, &c.:" and he adds, "that this practice is supported by some small number of trials." But the particulars of the success alluded to, are not given.

Dr. Shoolbred finds, that a trial of it was made at Edinburgh, more than sixty years ago, by Dr. Rutherford, who took away gradually sixty ounces of blood from a patient, who had already been bled the same morning. As the patient lived forty-eight hours after the large bleeding, the method was probably tried somewhat early in the disease; and the case may therefore be set down as a fair instance of the failure of the practice. The trials which have been made in this country of the practice of bleeding, in cases of hydrophobia, since the receipt of the above reports from India, I am sorry to say, have not confirmed its efficacy.

Bleeding was also recommended in cases of hydrophobia, by Poupart.—(See *Hist. de l'Acad. Royale des Sciences pour l'année* 1699, *p.* 48.) The practice is likewise mentioned in the *Medical Essays of Edinburgh, vol.* 5, *part* 2, § 5; *and in the writings of Dr. Rush.* See also *Dr. Burton's Case, Phil. Mag. August*, 1805.

Early excision, or amputation of the bitten parts, the application of cupping glasses to the wound, or the removal of atmospheric pressure, as recommended by Dr. Barry (See *Experimental Researches, &c. Lond.* 1826); the injection of warm water into the veins, and bleeding ad deliquium in the early stage, are the plans which have most evidence in their favour. It was observed by a critical writer, before the experiment of injecting water had been made, "That experience authorises the placing confidence in bleeding ad deliquium; on vomiting; and perhaps on the use of atropa belladonna; and on tobacco exhibited as a clyster. That it is probable, advantage would result from the combined employment of bleeding, vomiting (See *Dr. Satterly's Obs. in Medical Trans. vol.* 4), and purging in the early part of the disease. That analogy recommends the trial of spirit of turpentine in the convulsive stage of the disease."—(*Med. Repository, vol.* 3, *p.* 54.) In one case, in which oil of turpentine was copiously given, both in electuary and clysters, the patient died on the fourth day.—*Med. Repository, No. for October*, 1822.

[In the last republication of Mr. Cooper's Dictionary in this country, Dr. Samuel L. Mitchill furnished a letter addressed to himself, enclosing "a memorial read before the Medico-Physical Society of Moscow, by Dr Michel Marochetti, member of said society, and attending physician at the Gallitzir Hospital." It is entitled, "Observations on Hydrophobia, containing certain indications for ascertaining the existence of the hydrophobic poison in an individual, and the means of preventing its development by destroying its germ."

The "certain indications" to which this Russian physician refers, and on which he relies for ascertaining the existence of the rabid poison in an individual, are the appearance of two small tumours, one on either side of the frenum linguæ, within six weeks of the bite of a rabid animal.

He states, as the result of his observation, that it is necessary to examine the lower side of the tongue twice a day for six weeks after the bite; and this frequent inspection is necessary, because the tumours only exist twenty-four hours, when the virus becomes reab-

sorbed, and these two irregular tumours disappear, and the case terminates fatally.

He directs that these tumours be *cauterized* so soon as they are visible, or, what is better, opened with a small sharp lancet, when a *sanious* lymph, somewhat *greenish*, will escape, which is the true poison, and which the patient must spit out. The mouth is then to be washed with a decoction of the *tops* and *flowers* of the genista lateo tinctoria (Dya's broom). This same decoction is to be drunk to the extent of a pound and a half per day, during the six weeks the patient is under examination. And these means, Dr. M. asserts, from his personal experience in the treatment of numerous cases, will prevent the development of the virus, by destroying its germ.

What attention this Russian practice, which may be called a discovery, has attracted in Great Britain or the continent, Mr. Cooper must have had the means of knowing, and yet he is silent on the subject; whence we may conclude, it is not relied on in England. In this country, there is little confidence among the profession in any curative for hydrophobia; and physicians in America generally concur in these two important facts, as Mr. Cooper calls them: first, the disease may often be prevented: secondly, it can hardly ever be cured.

There is so much ambiguity about this subject, that it becomes us to be modest in deciding a patient to have hydrophobia, for scarcely a symptom belonging to it is invariable in every case; and many of the cures reported, are, doubtless, modifications of hysteria. I have seen more than one of these so called, because the patient had been bitten by a dog, months, or years before, without any evidence of his being rabid.—*Reese.*]

HYDROPHTHALMIA. (From ὕδωρ, water, and ὀφθαλμὸς, the eye.) *Dropsy of the Eye.*

Hydrophthalmus; Hydrophthalmos. Also *Buphthalmos*, or ox-eye. In the eye, as in other organs, dropsy arises from a disproportion taking place between the action of the secerning arteries, by which the fluid is deposited in the part, and the action of the absorbent vessels, by which it is taken up, and returned to the circulation; and according to this principle, the disease may be supposed to depend, either upon the secretion being too rapid, or absorption slower, than is proportionate to the natural activity of the vessels by which the secretion of the humours of the eye is effected.

According to Beer, dropsy of the eye is seldom entirely a local disease, but at least is generally combined with an unhealthy constitution, or is a mere symptomatic effect of some other dropsical affection, anasarca, hydrocephalus, &c. Sometimes it appears as a symptom of chlorosis. Beer adds, that the disease may originate either from a preternatural accumulation of the aqueous humour; from that of the vitreous humour; or from an immoderate accumulation of both these humours together.—(*Lehre, von den Augenkr. b.* 2, *p.* 616, *Wein*, 1817.) When the vitreous humour collects in this manner it usually loses its natural consistence, and becomes thinner and more watery.—(*Richter, Anfangsgr. b.* 3, *p.* 392.)

Professor Beer states, that in the case proceeding from a morbid quantity of the aqueous humour, the first indication of the disease is an increase in the dimensions of the cornea, attended with a manifest enlargement of the anterior chamber. The cornea may become, in this manner, two, three, or even four times wider than natural, without bursting or losing its transparency; for, though a turbid appearance is discernible, this depends rather upon the state of the aqueous humour itself. The iris, which in the very commencement of the disease begins to lose its mobility, soon becomes completely motionless, and acquires a duller colour; the pupil always remaining in the mid-state

between contraction and dilatation. In the eyeball an annoying sense of pressure, tension, and heaviness is felt rather than actual pain. In the beginning of the disease there is a considerable degree of far-sightedness, or presbyopia, which soon changes into a true amaurotic weakness of sight, but never terminates in perfect amaurosis. The free motions of the eyeball are more and more interrupted in proportion as the organ grows larger, and it has invariably a hard feel, while the sclerotica, to the distance of two lines from the margin of the cornea, is as bluish as it is in the new-born infant.

Respecting the precise cause of the accumulation of the aqueous humour, Beer offers no observation worthy of repetition, excepting perhaps that in which he reminds us, that a similar collection happens apparently as an effect of the conical staphyloma of the whole cornea.—(See also *Wardrop's Essays on the Morbid Anatomy of the Eye, vol. 5, p.* 19.) Indeed, as far as our knowledge yet extends, it is impossible to say whether the changes of the cornea are, in the present disease, to be regarded as the cause or the effect of the increased quantity of the aqueous humour, or whether, as seems to be most probable, both phenomena are only effects of one and the same cause. The examples somewhat repugnant to this idea, are those referred to by Beer as symptomatic of other dropsical affections. On the other hand, Mr. Wardrop has never seen a preternatural collection of the aqueous humour without its being accompanied with disease of the coats of the eye.—(*Vol. cit. p.* 20.)

In hydrophthalmia the prognosis is generally unfavourable, and when the sight is nearly or quite lost, scarcely any hope can be entertained, either of restoring vision or preserving the shape of the eye. Yet, according to Beer, things are not always quite so unpromising in the preceding form of the disease, especially when the surgeon is consulted in time, and the patient's constitution is not exceedingly impaired. The same experienced author has never seen any instance in which the eye spontaneously burst: on the contrary, when the habit was decidedly bad, and the treatment ineffectual, the disease became gradually conjoined with the second species of dropsy of the eye, and terminated in a frightful disfigurement of the whole organ, and death. On dissection, the innermost textures of the part were found spoiled and disorganized, and sometimes even the orbit itself carious.—(*Vol. cit. p.* 619.) With respect to the treatment, Beer thinks, that this must depend very much upon the nature of the primary disease to which the dropsical affection is ascribable as an effect. He has known great benefit sometimes produced by the submuriate of mercury, combined with digitalis, and a drink containing supertartrate of potassa and borax. When the disease has been preceded by the sudden cure of any cutaneous disease, he has faith in the method of attempting to restore the affection of the skin by inoculation, or if that be impracticable, by stimulating its surface with antimonial ointment, or making an issue. This plan is to be aided with internal alterative medicines, such as camphor, the sulphur auratum antimonii, and flowers of sulphur. The local applications, which he prefers in the early stage, are warm dry bags filled with aromatic herbs, and rubbing the parts about the eyebrow, sometimes with mercurial ointment, sometimes with a mixture of æther and liquor ammoniæ. But when the disease has made considerable progress, and vision is either weak or nearly lost, while the sclerotica near the cornea is not much discoloured, and there are no appearances of a varicose affection of the blood-vessels of the organ, Beer recommends making a puncture with a small lancet, in the lowest part of the cornea, half a line from the sclerotica, so as to discharge the aqueous humour. The anterior chamber is then to be kept empty for several days or weeks, if possible, by re-opening the small wound every day with the point of the lancet.—(See also *Richter's Anfangsgr. b.* 3, *p.* 403.) After the operation, the eye is to be dressed in the same way as after the extraction of a cataract.—(See *Cataract.*) Previously to the paracentesis, Beer has often seen every general and local means perfectly useless, but highly beneficial, as soon as that operation had been practised. Even when the paracentesis fails in bringing about a permanent cure, it may still be resorted to as a palliative with great advantage, and be often beneficially repeated, if care be taken not to make the puncture too large. However, when the blood-vessels are generally varicose, and the constitution very bad, such operation is apt to excite violent inflammation, suppuration, and even sloughing of the organ, attended with imminent danger to the patient's life.—(*Beer, vol. cit. p.* 620–622.)

With regard to the second species of hydrophthalmia, or that depending upon a preternatural accumulation of the vitreous humour, Beer states that, in this case, it is chiefly the posterior part of the eyeball which is enlarged, so that the whole organ acquires a conical shape, in which the cornea very much participates. The latter membrane remains unaltered in regard to its diameter; but it is more convex than natural, and its transparency is perfect. It is observed by Mr. Wardrop (*on the Morbid Anatomy of the Eye, vol.* 2, *p.* 126), that an increase in the quantity of the vitreous humour happens not unfrequently in staphyloma, in which disease, he says, the enlargement of the eyeball will generally be found to arise more from an increase in the quantity of the vitreous than of the aqueous humour, and he then expresses his belief, that the case adduced by Scarpa to illustrate the pathology of hydrophthalmia, and cited in the ensuing part of this article, was an example of staphyloma. Be this as it may, one character constant in staphyloma is often absent in hydrophthalmia; I mean opacity of the cornea. In the case which consists in an immoderate collection of the aqueous humour, the anterior chamber is always enlarged: on the contrary, in the present form of the disease, that cavity is manifestly lessened, for the motionless iris is gradually forced so much towards the cornea, that at length the chamber in question almost completely disappears. However, the colour of the iris undergoes no change, and the pupil is always rather diminutive. Around the cornea, the sclerotica is rendered bluish by distention, with a somewhat smutty tinge. In the early stage the patient is affected with short-sightedness, *myopia;* but his power of vision is always seriously diminished, and, at last, is so totally destroyed, that not a ray of light can be perceived. The motions of the globe of the eye and eyelids are lessened or impeded at a still earlier period than in the first species of hydrophthalmia, and to the touch the organ seems like an egg-shaped stone. The very commencement of the disease is attended with pain, which daily becomes more and more severe, and at length is not confined to the eye and its vicinity, but affects all the side of the head, the teeth, and neck, being sometimes so violent as almost to bereave the patient of his senses, who urgently begs the surgeon to puncture the eye, or even is driven by desperation to do it himself, as Beer once knew happen. Even while the pain is less afflicting, the patient is deprived of his sleep and appetite.—(*Beer, vol. cit. p.* 623.) Though an increase in the quantity of the vitreous or aqueous humour has generally been treated of as a distinct disease, and denominated hydrophthalmia, Mr. Wardrop has never seen a dropsy of the eye, without an accompanying disease of the sclerotic coat, or cornea.—(*On the Morbid Anatomy of the Eye, vol.* 2, *p.* 126.) Beer offers no valuable remark on the causes of the preceding form of hydrophthalmia, his account of the connexion with scrofula and syphilis being mere conjecture, though delivered as a positive matter of fact. However, another position offered in the paragraph, concerning the prognosis, seems more correct; viz. that as the disease is almost always conjoined with an unhealthy constitution, there can be scarcely any hope of a radical cure. Beer's opinion also is, that when the disease has made such progress, that not a ray can be discerned, and the pain in the eye and head so violent, by day and night, that the sleep, appetite, and even the senses are lost; it is fortunate, if only the most perilous symptoms can be obviated by palliative treatment; for the preservation of a good-shaped eye is then quite out of the question. And even in the most favourable cases, the utmost which can be expected is to stop the farther advance of the disease; a perfect cure being extremely rare.

According to Beer, the first indication is to improve the state of the health by medicines and regimen; for unless this object be effected, no expectation of curing the dropsical affection of the eye can be entertained. For this purpose a long time will be requisite; and as for local treatment in this case, little or nothing can be

accomplished by it. Hence, the disease often continues to grow worse and worse, and, when the pain becomes violent, the best thing which the surgeon can do, both with the view to the functions of the organ, and its form, is to let out the aqueous humour. But Beer reprobates, in the strongest terms, the plan sometimes recommended, of plunging a trocar through the sclerotica into the vitreous humour, and keeping the tube introduced until a certain quantity of that humour is discharged. The usual result of such practice is a carcinomatous disease of the eye, terminating in death, which the removal of the part will not prevent. The method preferred by Beer is that which is mentioned by Richter (*Anfangsg*, *b.* 3, *p.* 400), and consists in opening the cornea and capsule of the lens, as in the extraction of the cataract, discharging the lens and vitreous humour, and letting the coats of the eye collapse; but in order to prevent any re-accumulation of the fluid, he afterward cuts away a little bit of the flap of the cornea. The eye is then to be dressed in the same manner as after the extraction of the cataract.—(See *Cataract*.) The third species of hydrophthalmia, or that produced by an accumulation both of the aqueous and vitreous humours together, is excellently described by Scarpa. He observes, that in every case on which he has performed the operation, and in other examinations of the different stages of the disease made on the dead subject, he has constantly found the vitreous humour more or less altered in its organization, liquefied, and converted into water, according as the disease was ancient or recent. In some instances he could not distinguish whether the increased quantity of the vitreous or aqueous humour had most share in the formation of the disease.

Scarpa also dissected a dropsical eye taken from the body of a child. The vitreous humour was not only wanting in this eye, and the cavity destined for its reception filled with water, but the vitreous tunic was converted into a substance partly of a spongy, partly of a fatty nature. This dropsical eye was one-third larger than natural. The sclerotica was not thinner than that of the other eye: but in consequence of being yielding, flaccid, and separated from the choroides, it had lost its plumpness and globular shape. The cornea formed a disc one-third larger than that of this membrane in a sound state; it did not retain its natural pulpy structure, and was obviously thinner than the cornea of the healthy eye. There was a considerable quantity of an aqueous, reddish fluid, between the cornea and iris. The crystalline lens, with its opaque capsule, had been pushed forward a little way into the anterior chamber, but could not advance farther, on account of a firm adhesion which the capsule had contracted with the iris around the edge of the pupil. As soon as the capsule was opened the lens issued from it, half dissolved, the rest exceedingly soft. It was impossible to detach the whole of the posterior layer of the capsule from a hard substance, which seemed to be the altered membrane of the vitreous humour. Scarpa, therefore, slit open the choroides from the ciliary ligament to the bottom of the eye, when a considerable quantity of a reddish aqueous fluid gushed out, without, however, one particle of the vitreous humour. In lieu of the latter body there was found a small cylinder, of a substance, partly of a fungous, partly of a fatty nature, surrounded with a good deal of water, which was effused in the longitudinal axis of the eye, from the entrance of the optic nerve, as far as the ciliary ligament, or that hard substance to which the posterior layer of the capsule firmly adhered. This little cylinder was covered, for the extent of two lines and a half forwards from the entrance of the optic nerve, by a stratum of whitish matter reflected on itself, like the epiploon, when raised towards the fundus of the stomach. Scarpa conceived that this stratum of whitish matter was the relics of the unorganized retina; for, on pouring rectified spirits of wine on the whole inner surface of the choroides, and the little cylindrical body, he found no vestiges of the retina on this membrane, and that the whitish substance, which was reflected on itself, became very firm, just as the retina does when immersed in spirits of wine. Both the cylinder and the indurated substance occupying the place of the ciliary body were manifestly only the membrane of the vitreous humour, destitute of water, and converted, as was described, into a substance, partly of a spongy, partly of an adipose nature. It is not easy to determine whether this altered state of the vitreous tunic had preceded, or was a consequence of the dropsy of the eye. However it may be, this fact, in conjunction with several other similar ones that Scarpa has met with, in which he found no vitreous humour in the posterior cavity of the eye, but only water or a bloody lymph, tends very much to establish the fact, that this disease principally consists of a morbific secretion of the vitreous humour, and occasionally, also, of a strange degeneration of the alveolary membrane, by which this humour is formed. Scarpa refers to a similar case.—(See *Med. Obs. and Inquiries*, *vol.* 3, *art.* 14.)

The augmentation in the secretion of the aqueous fluid, both in the cells of the vitreous humour and out of them, after they have been ruptured from excessive distention, together with a debilitated action of the absorbent system of the eye affected, Scarpa regards as the probable cause of the morbific accumulation of humours in the eye. From such a lodgment, and successive increase of the vitreous and aqueous humours, the eyeball at first necessarily assumes an oval shape, ending at the point of the cornea; the organ enlarges in all dimensions: and in the end, it projects from the orbit in such a manner, that it cannot be covered by the eyelids, disfiguring the patient's face as much as if an ox's eye were placed in the orbit.

This disease (says Scarpa) is sometimes preceded by blows on the eye or temple; sometimes by an obstinate internal ophthalmy. In other instances, it is preceded by no inconvenience, except an uneasy sensation of tumefaction and distention in the orbits, a difficulty of moving the eyeball, and a considerable impairment of sight. Lastly, it is sometimes preceded by none of these causes, or no other obvious one whatever, especially when the complaint occurs in children of very tender age, from whom no information can be obtained. As soon as the eye has assumed an oval form, and the anterior chamber has become preternaturally capacious, the iris seems situated farther backward than usual, and tremulates, in a very singular way, on the slightest motion of the eyeball. The pupil remains dilated in every degree of light, while the crystalline is sometimes brownish from the very beginning of the disease; and sometimes it does not become cloudy till the affection has arrived at its highest pitch. The complaint then becomes stationary; and as the crystalline is not deeply opaque, the patient can distinguish light from darkness, and in some degree, the outlines of objects and brilliant colours. But when the eye has acquired a larger volume, and the whole crystalline has become opaque, the retina at last remains in a state of complete paralysis.

In the last stage of the disease, to which the term bupthalmos, or ox-eye, is properly applicable, when the dropsical eye projects from the orbit, so as not to admit of being covered by the eyelids, with the inconveniences already enumerated, says Scarpa, others associate themselves, arising from the friction of the ciliæ, the secretion of gum, the flux of tears, the ulceration of the lower eyelid, on which the eye rests, and the excoriation of the eye itself. Hence, the dropsical eye is gradually attacked with violent ophthalmies, attended with intolerable pains in the part affected, and the whole head. The ulceration, also, does not always confine itself within certain limits; but continues to spread, first depriving the cornea of its transparency, next consuming the sclerotica, and lastly, destroying progressively the other component parts of the eyeball.

At the first appearance of dropsy of the eye, many surgeons recommend mercurials, the extract of cicuta, and of pulsatilla nigricans; and astringent collyria, a seton in the nape of the neck, and compression of the projecting eye. However, Scarpa has never yet met with a single well detailed history of a dropsy of the eye cured by means of the above-mentioned internal medicines. With regard to externals, he has learned from his own experience, that when the disorder is manifest, astringent and corroborant collyria, as well as compression of the protuberant eye, are highly prejudicial. In such circumstances, making a seton in the nape of the neck, frequently bathing the eye in a lotion of mallows, and applying to it a poultice, composed of the same plant, have enabled him to calm, for a time, that disagreeable sense of distention in the orbit, and over the forehead and temple of the same

side, of which patients in this state make so much complaint, especially when they are affected with a recurrence of ophthalmy. But as soon as the eyeball begins to protrude from the orbit, and project beyond the eyelids, he thinks there is no means of opposing the very grievous dangers which the dropsy of the eye threatens, except an operation, which consists in evacuating by an incision, the superabundant humours, then exciting gentle inflammation of the membranes, and suppuration within this organ, so as to make it contract and shrink into the bottom of the orbit. To defer the operation any longer would be abandoning the patient to the constant inconvenience of an habitual ophthalmy, the danger of an ulceration of the eyeball and subjacent eyelid, and what is worse, of carcinoma of the whole eye, with great peril to the patient.

Beer's prognosis in the third species of hydrophthalmia is at least as discouraging as that made by Scarpa; for the rapidity of the disease is said to be such as leaves scarcely a possibility of benefit being effected by any mode of treatment, and the case usually terminates in a carcinomatous exophthalmia and death. These melancholy events are said, by Beer, to be accelerated by paracentesis of the eye, however executed; and he thinks, that the sole chance of stopping the progress of the disease depends upon an endeavour being made in its very commencement to improve the general health, though he owns, that success is to be regarded as a very rare and fortunate occurrence. The same author has no faith in any local treatment, and when the disease is advanced, he considers the extirpation of the eye the only rational expedient, though very precarious in its result.—(*Lehre von den Augenkr. b.* 2, *p.* 628, 629.)

The main point on which Scarpa differs from Beer, is that respecting the effects of discharging the humours of the eye; a practice which the former represents as useful, even in cases where the hydrophthalmia combines an accumulation both of the aqueous and vitreous humours. In former times, says Scarpa, paracentesis of the eyeball was greatly extolled. Nuck, one of the promoters of this operation, punctured the eye with a trocar, exactly in the centre of the cornea.—(*De Duct. Ocul. Aquos. p.* 120.) It has since been thought better to puncture the sclerotica about two lines from the junction of this membrane with the cornea, and such a small quantity of the vitreous humour may be more easily discharged at the same time with the aqueous, as may be deemed adequate to effect a diminution of the eyeball.

According to Scarpa, paracentesis of the eye, done so as merely to discharge the humours, can never be a means of curing dropsy of the eye, unless the puncture made with the trocar excite inflammation and suppuration, and afterward a concretion of the membranes composing the eyeball. In a young man at Breda, Nuck was obliged to puncture the eye five several times; on the fifth time of doing this, it was necessary to suck through the cannula of the trocar, in order to evacuate the greatest possible quantity of the vitreous humour; and, lastly, a plate of lead was put between the eyelids and eyeball, for the purpose of making continual pressure on the eye, in its empty shrivelled state. In a woman at the Hague, he twice punctured the eye in vain; and she submitted, two or three times afterward, to the same operation, but with what degree of success is not specified. Scarpa has no difficulty in believing, that a radical cure of the dropsy has sometimes been accomplished by means of the puncture, after the trocar, and other similar hard substances, have been repeatedly introduced into the eye, through the cannula of that instrument; but this success can never be attributed to the mere evacuation of the superabundance of the vitreous and aqueous humour; though it may be referred to that circumstance, conjoined with the irritation produced by the cannula, or the tents with which Mauchart kept open the wound.

Scarpa condemns the plan of making a circular incision through the sclerotica, as disadvantageous, and even dangerous. In fact, this circular recision is constantly followed by the most aggravated symptoms, particularly frequent hemorrhages, an accumulation of grumous blood at the bottom of the eyeball, vehement inflammation of the eye, eyelids, and head, obstinate vomitings, convulsions, delirium, and the most imminent danger to the patient's life. Such modern surgeons as have faithfully published the results of their practice on this point, namely, M. Louis (*Mém. de l'Acad. de Chir. t.* 13, *p.* 289, 290), Marchan (*Journal de Méd. de Paris, Janvier*, 1770; *Sur deux Exophthalmies, ou Grosseurs contre Nature du Globe de l'Œil*), and Terras (*Ibidem, Mars*, 1776; *Sur l'Hydrophthalmie*), have ingenuously declared, that after performing the circular recision of dropsical eyes in the sclerotica, they had the greatest motives for repenting of what they had done. Scarpa prefers making a circular section, about three lines in breadth, at the summit or centre of the cornea of the dropsical eye, as directed by Celsus in cases of staphyloma.

Whether the cornea be transparent or not, as sight is irrevocably lost, the surgeon must introduce a small bistoury across the apex, or middle of the cornea, at one line and a half from its central point; and then, by pushing the instrument from one towards the other canthus of the eye, he will cut the lower part of the cornea in a semicircular manner. The segment of the cornea being next elevated with the forceps, the operator is to turn the edge of the knife upwards, and complete the work by a circular removal of as much of the centre of the cornea as is equal to three lines in diameter. Through this circular opening made in the centre of the cornea, the surgeon may, by means of gentle pressure, discharge as much of the superabundant humours in the eye as is requisite to make the eyeball diminish, and return into the orbit, so as to be covered by the eyelids. As for the rest of the humour lodged in the eye, it will gradually escape of itself, through the circular opening in the cornea, without any more pressure being made.

Until the appearance of the inflammation, that is, until the third or fifth day after the operation, the dressings are to consist of the application of a compress of dry lint supported by a bandage. As soon as inflammation and tumefaction invade the eye operated on, and the eyelids, the surgeon is to employ such internal remedies as are calculated to moderate the progress of inflammation; and he is to cover the eyelids with a bread and milk poultice, which must be renewed at least once every two hours. It is a very frequent result, both in the staphyloma and dropsy of the eye, that on the first appearance of inflammation, the eyeball on which the operation has been done augments and protrudes again from the eyelids, in the same way as before the operation. In this circumstance, Scarpa directs the projecting part of the eyeball to be covered with a piece of fine linen, smeared with a liniment of oil and wax, or the yelk of an egg and oleum hyperici; the application of the bread and milk poultice being continued over such dressing. When the interior of the eye begins to suppurate, the swelling of the eyelids decreases, and the eyeball diminishes in size, and returns gradually into the orbit. This state of suppuration may be known by observing, that the dressings are smeared with a viscid lymph, blended with a portion of the humours of the eye, which incessantly issue from the centre of the cornea; and by noticing the appearance of the margin of the recision, which is changed into a circle of a whitish substance resembling the rind of bacon, which is afterward detached, like a slough, so as to leave a small ulcer of a very healthy colour. This ulcer, as well as the whole eyeball, contracts and becomes entirely cicatrized, leaving every opportunity for the placing of an artificial eye between the eyelids and the stump of the eyeball.

If a mild inflammation and suppuration in the interior of the eye should not take place on the fifth day, Scarpa exposes the eye to the air, or removes a circular portion of the cornea, half a line in breadth, or little more, by means of the forceps and curved scissors. The foregoing practice is certainly preferable to that advised by Richter, who, when the eyesight is lost, and the object is merely to discharge the humours and let the eye collapse, sometimes makes a crucial division of the cornea, and removes the four flaps or angles, or even cuts away the whole of the anterior part of the eyeball through the sclerotica.—(*Anfangsgr. b.* 3, *p.* 404.) In order to lessen the bulk of the eye, the late Mr. Ford, in one instance, passed a seton through the front of the organ, with apparent success.—(See *Med. Communications, vol.* 1.) HYDROPS. (From ὕδωρ, water.) A dropsy, or morbid accumulation of water. For *hydrops articuli* refer to *Joints, Diseases of;* for *hydrops oculi*, see the foregoing article. With regard to *hydrops pectoris, hydrothorax*, or *dropsy of the chest*, as it is altogether a medical case, an account of its symptoms and treatment will hardly be required in this Dictionary. The only concern which a surgeon has with the disease is, being occasionally required to make an opening for the discharge of the water.—(See *Paracentesis Thoracis.*)

HYDROSARCOCELE. (From ὕδωρ, water; σάοξ, flesh; and κήλη, a tumour.) A sarcocele, attended with a collection of fluid in the tunica vaginalis.

HYMEN, IMPERFORATE. The inconveniences brought on by such a cause, and the mode of relief, are explained in the article *Vagina.*

A continuation of the hymen over a part of the orifice of the meatus urinarius may produce great pain and difficulty in making water, and symptoms which may give rise to suspicion of stone. For a case illustrating the truth of this observation, see *Warner's Cases in Surgery, p.* 276, *edit.* 4.

HYPOPIUM, or HYPOPYON. (From ὑπὸ, under; and πύον, pus.) An accumulation of the glutinous yellowish fluid, like pus, in the anterior chamber of the aqueous humour; and frequently, also, in the posterior one, in consequence of severe acute ophthalmy, particularly the internal species, or what is now so well known under the name of iritis.

The viscid matter of hypopium, though commonly called pus, Scarpa regards as coagulating lymph. The symptoms portending an extravasation of coagulating lymph in the eye, or an hypopium, are the same as those which occur in the highest stage of violent acute ophthalmy: viz. prodigious tumefaction of the eyelids; the same redness and swelling of the conjunctiva, as in chemosis; burning heat and pain in the eye; pains in the eyebrow and nape of the neck; fever, restlessness, aversion to the faintest light, and a contracted state of the pupil.

As soon as the hypopium begins to form (says Scarpa), a yellowish semilunar streak makes its appearance at the bottom of the anterior chamber, and regularly as the glutinous fluid is secreted from the inflamed internal membranes of the eye, so as to pass through the pupil and fall into the aqueous humour, it increases in all dimensions, and gradually obscures the iris, first at its inferior part, next where it forms the pupil, and lastly the whole circumference of this membrane. As long as the inflammatory stage of violent ophthalmy lasts, the hypopium never fails to enlarge; but immediately this stage ceases, and the ophthalmy enters its second period, or that dependent on local weakness, the quantity of coagulating lymph, forming the hypopium, leaves off increasing, and from that moment is disposed to diminish.

This fact sufficiently evinces (continues this eminent professor) how important it is, in order to check the progress of the hypopium, to employ, with the utmost care, the most effectual means for checking the attack of violent ophthalmy in its first stage. He recommends copious evacuations of blood, both generally and topically, to be speedily put in practice; and when chemosis exists, the conjunctiva to be divided; mild aperients given, blisters applied to the nape of the neck, little bags of emollient herbs to the eye, and other measures employed. It will be known that they have fulfilled the indication by noticing that some days after the adoption of such treatment, though there may still be redness of the conjunctiva and eyelids, the lancinating pains in the eye abate, the heat considerably diminishes, the fever subsides, quietude and sleep are restored, the motion of the eye becomes free, and lastly, the collection of viscid matter forming the hypopium becomes stationary. It is not unfrequent to see, especially among the lower orders of the people, persons affected with the second stage of severe acute ophthalmy, bearing this collection of coagulating lymph, in the chambers of the aqueous humour, with the greatest indifference, and without complaining of any of those symptoms which characterize the acute stage of ophthalmy. It is only at this crisis, or at the termination of the acute stage of violent inflammation of the eye, that the enlargement of the hypopium ceases, and the coagulating lymph begins to be absorbed, provided this salutary operation of nature be not impeded nor retarded by any injudicious regimen. However, if Scarpa had also been aware of the great efficacy of mercury in arresting the effusion of lymph, I can hardly doubt, that he would have modified some of the preceding observations as well as his practice; a subject to which I shall presently return.

Scarpa states, that persons little versed in the treatment of diseases of the eyes, would fancy, that the most expeditious and efficacious mode of curing an hypopium, after it has become stationary in the second stage of severe acute ophthalmy, would be that of opening the cornea at its most depending part, in order to procure a speedy exit for the matter collected in the chambers of the aqueous humour; especially as this was once the common doctrine. But experience shows, that dividing the cornea in such circumstances is seldom successful, and most frequently gives rise to evils worse than the hypopium itself, notwithstanding the modification suggested by Richter (*Obs. Chir. fasc.* 1, *chap.* 12), not to evacuate the whole of the matter at once, nor to promote its discharge by repeated pressure and injections, but to allow it to flow slowly out of itself. The wound made at the lower part of the cornea for evacuating the matter of the hypopium, small as the incision may be, most commonly reproduces severe acute ophthalmy, and a greater effusion of coagulating lymph into the chambers of the aqueous humour. Besides, after opening the cornea, if the matter of the hypopium were allowed to escape gradually of itself, it would be several days in being completely discharged, on account of its viscidity. During this time the glutinous lymph would keep the edges of the wound of the cornea dilated, and make them suppurate. Thus the incision would be converted into an ulcer, through which the aqueous humour would escape, and even a fold of the iris. Opening the cornea, therefore, only converts the hypopium into an ulcer of that membrane, attended with a prolapsus of the iris, and occasionally of the crystalline itself. Nor can any inference be drawn in favour of making an artificial opening, during the stationary state of an hypopium in the second stage of severe acute ophthalmy, from the matter of the hypopium having sometimes made its way spontaneously through a narrow aperture in the cornea with a successful result. For there is a wide difference between the effects of a spontaneous opening in a natural or preternatural cavity of the animal body, or of one made with caustic, and the consequences of an opening made with a cutting instrument. In the first two methods the subsequent symptoms are constantly milder than in the last. Besides, even in the instance in which a spontaneous discharge of the hypopium takes place through the cornea, an escape of the aqueous humour, and a prolapsus of the iris, not unfrequently ensue; consequently, the spontaneous evacuation of the hypopium cannot justly form a rule for the treatment of the disease. There is only one case in which dividing the cornea, in order to discharge an hypopium, is not only useful but indispensable; this is, when there is such an immense quantity of coagulating lymph, extravasated in the eye, that the excessive distention which it produces of all the coats of this organ, occasions symptoms so vehement as not only threaten the entire destruction of the eye, but even endanger the life of the patient. But this particular case cannot serve (says Scarpa) as a model for the treatment of ordinary cases.

The dispersion of the hypopium, by means of absorption, forms the primary indication at which the surgeon should aim. In order to stop its progress, the most efficacious method is to subdue the first violence

of the inflammation, and to shorten its acute stage, by the free employment of antiphlogistic treatment and the use of mild emollient, topical remedies. And, in conjunction with these means, there can now be no doubt that the practice of Brüel, published in 1809, as will be mentioned at the close of this article, ought to be followed: I mean the quick exhibition of the submuriate of mercury, which has also been found at the London Ophthalmic Infirmary the most powerful means of checking the effusion of lymph in the eye.—(See *Saunders's Work on the Eye, ed. 2, and a Synopsis of the Diseases of the Eye, by B. Travers, p.* 135.)

If this treatment answer, the incipient collection of coagulating lymph at the bottom of the anterior chamber of the aqueous humour, not only ceases to augment, but also, in proportion as the severe ophthalmy disappears, the absorbent system takes up the heterogenous fluid extravasated in the eye, and the white or yellow speck, shaped like a crescent, situated at the bottom of the anterior chamber, gradually diminishes, and is at last entirely dispersed. Such, in short, is the successful termination of an hypopium, whenever the disease is properly treated at its commencement, and the acute stage of severe ophthalmy is promptly checked by internal antiphlogistic means and emollient applications. But, in consequence of the inflammatory period of the severe ophthalmy having resisted, in an uncommon manner, the best means, or because such means have been employed too late, it sometimes happens that the coagulating lymph collected in the anterior chamber is so abundant, even after the acute stage of ophthalmy, that it continues for a long time to cloud the eye and intercept vision. Scarpa has often seen patients, especially paupers, who, from indolence, negligence, or ill treatment, remained a long time after the cessation of the inflammatory stage of ophthalmy, with the anterior chamber nearly filled with the glutinous matter of hypopium. When the inflammation had ceased, these unhappy persons wandered about the streets almost indifferent, and without complaining of pain, or any other inconvenience, than the difficulty of seeing with the eye affected. In this second stage of the ophthalmy, the resolution of hypopium obviously cannot be accomplished by the same means, nor with equal celerity, as in the first. At this crisis, the great quantity and density of the glutinous matter extravasated, and the atony of the vascular system of the eye, make it necessary to give nature sufficient time to dissipate the thick, tenacious matter, and at length to dispose it to be insensibly absorbed with the aqueous humour, which is continually undergoing a renovation. Hence it is right (says Scarpa) to adopt those means which are best calculated to invigorate the vascular system of the eye, more especially the lymphatics. This requires more or less time, according as the patient is advanced in years, of a relaxed fibre, and weak, or a young man of good constitution.

However, according to Scarpa, in the second stage of violent acute ophthalmy, complicated with hypopium, the surgeon should limit his efforts to the removal of every thing which may irritate the eye, or be likely to renew the inflammation; and he should only employ such means as are conducive to the resolution of the second inflammatory stage, depending on relaxation of the conjunctiva and its vessels, and such remedies as tend, at the same time, to invigorate the action of the absorbents. Therefore, in this state, he ought first to examine carefully the degree of irritability in the eye affected with the hypopium, by introducing, between the eye and eyelids, a few drops of vitriolic collyrium, containing the mucilage of quince seeds. Should the eye seem too strongly stimulated by this application, it must not be used, and little bags of warm mallows with a few grains of camphor are to be substituted for it. In the intervals, the vapours of the liquor ammon. comp. may be applied, and recourse had again to a blister on the nape of the neck. When the extreme sensibility of the eye is overcome, the zinc collyrium must be used again, afterward strengthened with a few drops of camphorated spirit. In this country, the exhibition of mercury would be generally deemed better practice than that here recommended by Scarpa. In proportion as the chronic opthalmy disappears, and the action of the absorbents is re-excited, the tenacious matter of the hypopicm divides first into several small masses; then dissolves still farther, and afterward decreases in quantity: descending towards the inferior segment of the cornea; and finally vanishing altogether. But Scarpa accurately observes, that the surgeon cannot always expect to be equally successful, whether the disease occur during the first or second stage of violent acute ophthalmy, if the tenacious lymph, suddenly extravasated in the interior of the eye, prevail in such quantity, as not only to fill, but strongly distend, the two chambers of the aqueous humour and the cornea in particular. In this state notwithstanding the most skilful treatment, the unpleasant complication is often followed by another inconvenience, still worse than the hypopium itself; viz ulceration, opacity, and bursting of the cornea.

The ulceration of the cornea ordinarily takes place with such celerity, that the surgeon seldom has time to prevent it. As soon as an aperture has been formed, the excessive abundance of coagulating lymph, contained in the eye, (sometimes named empyema oculi) begins to escape through it, and a degree of relief is experienced. But this melioration is not of long continuance; for scarcely is the glutinous fluid evacuated that distended the whole eye, and especially the cornea, when it is followed by a portion of the iris, which glides through the ulcerated aperture, protrudes externally, and constitutes the disease termed prolapsus of the iris.—(See *Iris, Prolapsus of.*) But if in such an emergency the cornea, already ulcerated, opaque, and greatly deranged in its organization, should not immediately burst, the surgeon is then constrained by the violence of the symptoms, depending on the prodigious distention of the eyeball, to make an opening in this membrane, in order to relieve the immense constriction, and even the danger in which life is placed.

Were there the least chance of restoring, in any degree, the transparency of the cornea, and the functions of the organs of vision, after opening the cornea, Scarpa acknowledges, that it would certainly be more prudent to make the opening at the lower part of this membrane. But in the case of empyema of the eye, now considered, in which the cornea is universally menaced with ulceration and opacity, and seems ready to slough, there can be no hope of its resuming its transparency at any point, and he therefore deems it the best and most expeditious method of relief to divide its centre with a small bistoury to the extent of a line and a half; and then to raise with a pair of forceps the little flap, and cut it away all round with one stroke of the scissors: so as to let the humours escape without any pressure.

The eye is to be covered with a bread and milk poultice, which is to be renewed every two hours, the use of such general remedies as are calculated to check the progress of acute inflammation, and to quiet the nervous system, not being omitted. In proportion as the interior of the eye suppurates, the eyeball gradually diminishes, shrinks into the orbit, and at length cicatrizes, leaving things in a favourable state for the application of an artifical eye.

When Scarpa delivers his opinion, that in the above aggravated form of hypopium there can be no chance of the cornea resuming its transparency at any point, I think his assertion rather imprudent. Nor, admitting its general truth, does it follow, as a matter of course, that it is necessary and right to cut away a piece of the centre of the cornea, and absolutely destroy whatever little chance may yet be left of saving the eye. In support of this remark let me contrast what Mr. Travers has said with the advice of Scarpa. "When the hypopium is so large as to rise towards the pupil, and the ulceration of the cornea is extending, I think its discharge *by section near the margin* advisable. If not too long delayed, the ulcerative process is checked by it, which would otherwise run into sloughing, and *the cornea recovers with only partial opacity and disfigurement.*"—(*Synopsis of the Diseases of the Eye, p.* 280.)

Mauchart de Hypopyo; Tubingæ, 1742. *C. P. Leporin, de Hypopyo*; 4*to. Goët*, 1778. *Goeldin, Diss. de Hypopyo; Erlang*, 1810. *Walther Merkwürdige, Heilung eines Eiterauges, &c.* 8*vo. Landshut*, 1819. *I observe, that in Hufeland and Himley's Journal for October* 1809, *p.* 93, *there is an account of the treatment of an hypopium, or case of effused lymph in the chambers of the eye, by exhibiting from* 12 *to* 18 *grains of the submuriate of mercury in the space of* 12 *hours, and then giving bark, while as an external application the tinct. opii croeat. was employed. Thus we see that the*

efficacy of mercury in checking the effusion of lymph in the eye, and promoting its absorption, has been known many years in Germany. A. HYSTEROTOMIA. (From ὑστερα, the womb, and τέμνω, to cut.)—See *Cæsarean Operation.*

I

IMPERFORATE HYMEN.—(See *Vagina.*)

INCARCERATION. This term is usually applied to cases of hernia, in the same sense as strangulation. When the viscera are pressed upon either by the opening through which they protrude, or by the parts themselves within the hernial sac, in such a degree, that the course of the intestinal matter to the anus is obstructed, and nausea, sickness, pain, and tension of the swelling and abdomen, &c. are occasioned, the rupture is said to be in a state of incarceration, or strangulation.

According to Professor Scarpa, however, an *incarcerated* and a *strangulated* hernia do not imply exactly the same thing. In the first case, says he, the course of the intestinal matter is interrupted, without any considerable impairment of the texture or vitality of the bowel. On the contrary, in the strangulated hernia, besides the obstruction to the course of the fecal matter, there is organic injury of the coats of the intestine, with loss of its vitality. The bowel that is merely incarcerated, resumes its functions immediately it is replaced in the abdomen; while that which is truly strangulated never returns to its natural state.—(*Traité des Hernies, p.* 251.) English surgeons do not adopt this distinction.

INCONTINENCE OF URINE.—(See *Urine, Incontinence of.*)

INFLAMMATION. (From *inflamma*, to burn.) By the term *inflammation*, is generally understood the state of a part, in which it is painful, hotter, redder, and somewhat more turgid than it naturally is; which topical symptoms, when present in any considerable degree, or when they affect very sensible parts, are attended with fever, or a general disturbance of the system.—(*Burns.*)

The susceptibility of the body for inflammation is of two kinds: the one *original*, constituting a part of the animal economy, and beyond the reach of human investigation; the other *acquired*, from the influence of climate, habits of life, and state of the mind over the constitution.—(*Hunter.*) The first kind of susceptibility, being innate, cannot be diminished by art; the second may be lessened by the mere avoidance of the particular causes on which it depends.

Inflammation may, with great propriety, be divided into *healthy* and *unhealthy*. Of the first, there can only be one kind, though divisible into different stages; of the second, there must be an infinite number of species, according to the peculiarities of different constitutions, and the nature of diseases, which are numberless.—(*Hunter.*) Another general division is into *common* and *specific* inflammation, the latter term implying that the affection has some strongly marked particularity about it, rendering it, in some degree, independent of such circumstances as would control and regulate the progress of common inflammation. Such are *venereal, variolous, vaccine, erysipelatous, gouty*, and *rheumatic* inflammations, &c. Inflammation may also be divided into the *acute* and *chronic*. This division of the subject is one of the most ancient, and seems to have obtained the sanction of all the best surgical writers. Healthy inflammation is invariably quick in its progress, for which reason it must always rank as an *acute* species of the affection. However, there are numerous inflammations, controlled by a diseased principle, which are quick in their progress, and are, therefore, to be considered as acute. Chronic inflammation, which will be treated of when I come to the subject of *tumours*, is always accompanied with diseased action.

My friend, Mr. James, of Exeter, justly impressed with the utility which would result from a good nosological arrangement of inflammation, has attempted to supply what must generally be allowed to be a great desideratum. To the division of inflammation into the *acute, sub-acute*, or *chronic*, he objects, that in many instances these are merely different stages of the same disease. The arrangement into the *adhesive, suppurative, ulcerative*, or *gangrenous* inflammation, he does not altogether approve, because it is merely founded on the modes in which either different, or, in some instances, the same kinds of inflammation terminate. Under the heads of *phlegmonous, erysipelatous*, and *gangrenous* inflammation, he argues, that diseases of the most opposite nature have been indiscriminately brought together. The disposition to terminate in gangrene, he admits, will afford a basis for subdivision, but not for primary separation. Mr. James makes some judicious observations on the arrangement of the kinds of inflammation, according to the elementary tissue in which they occur, as proposed by Dr. Carmichael Smith, Pinel, and Bichat. The tissues in question are five, and the doctrine supposes that the inflammation of each is essentially different. The first is phlegmonous inflammation, which affects the cellular membrane, including the parenchyma of the several viscera. The second is inflammation of serous membranes. The third, of mucous membranes. The fourth, which is named erysipelatous, is of the skin: and the fifth, termed rheumatic, belongs to fibrous structure. That inflammations differ materially from the circumstance of their affecting one of these elementary tissues rather than another, Mr. James freely admits; but the following objections appear to him fatal to this system, if they are true. 1. Different kinds of inflammation are liable to occur in the same tissue. 2. The same kind of inflammation is often met with in different tissues. 3. The same inflammation may be transferred from one to another; an argument, however, on which he lays less stress, as being difficult of direct proof.—(See *Obs. on the different Species of Inflammation, p.* 3—7, *8vo. Lond.* 1821.) Although difference of structure unquestionably accounts for some of the varieties in the appearance and character of inflammation, it will not sufficiently explain the principal diversities of this affection, to be taken as the foundation of a nosological arrangement, not only for the reasons pointed out by Mr. James, but because the common distinctions of inflammation at present in vogue, and some of which at least are obvious and striking, cannot be at all solved by any reference merely to texture. Nor did this theory satisfy Mr. Hunter, who observed, that if it were true, "we should soon be made acquainted with all the different inflammations in the same person, at the same time, and even in the same wound. For instance, in an amputation of a leg, where we cut through the skin, cellular membrane, muscle, tendon, periosteum, bone, and marrow, the skin should give us inflammation of its kind; the cellular membrane of its kind; the muscles of theirs, &c. &c.; but we find it is the same inflammation in them all." However, though Mr. Hunter did not admit the possibility of referring the different kinds of inflammation to peculiarities of texture, his doctrines assign to this cause considerable influence over every form of the disorder, as will be presently explained.

Indeed, it must after all be granted, that the inflammation of a membrane differs very much from that of a muscle; and that both differ from that of the skin. If also the common doctrine be true, that one peculiar kind of inflammation is seen in no other organ but the skin, we must here also admit the vast influence either of structure or of the particular nature of the

part, in determining at all events the seat of this inflammation.

The mode of reasoning, adopted by Mr. James, leads him to propose; 1st. The division of inflammations into two great classes, according to their disposition either to *be limited* by the effusion of organizable coagulable lymph, or to *spread*. 2dly. The orders are established on the principle of the *degree of connexion of the organ with the vital functions of the animal*; another cause, which exerts a predominant influence over the character of the inflammation; acts invariably, and, *cæteris paribus*, in the same degree; the constitutional sympathy being in proportion to the danger, the difficulty of resisting that danger, and of repairing the mischief done. 3dly. The genera are founded on the original disposition of inflammations to have particular modes of termination: thus, says Mr. James, in boil and whitlow, it is to suppurate; in carbuncle, to slough; and in mumps, to resolve; and this disposition is so strong, that it is very difficult to procure any other termination. It may happen, however, that there shall be more than one mode in which it (the inflammation) is disposed to terminate, as in either resolution, or suppuration, in sphacelus, or ulceration, &c.—(*Op. cit. p.* 13—16.) Mr. James conceives "that these general principles will perhaps afford a sufficient basis for such an arrangement, as shall be both natural and useful in its application to all kinds of common inflammation; gout, rheumatism, and scrofula having peculiarities, which require them to be separated. Also with respect to inflammations arising from external injuries, as they are more simple in their nature, may take place in sound constitutions, and are accompanied with disorganizations, which do not exist in other cases, Mr. James considers them as materially different. This author purposely excludes from his classification inflammations of the organs of sense, and of the bones, the peculiarities in their structure and functions rendering them fit subjects for separate description. With respect to Mr. James's nosological table of inflammation, I consider it very ingenious, and well deserving of the attention of the profession: I may say this, without at all involving myself in the hypothesis, that the limitation or spreading of the generality of inflammations, is a circumstance entirely dependent upon their disposition or indisposition to effuse organizable lymph. Mr. Hunter was well acquainted with the frequent usefulness of the adhesive inflammation in setting limits to disease, yet he did not venture to refer the circumscription of every inflammation to this cause, or the spreading of the disorder entirely to its absence. Nor, indeed, does it seem essential to Mr. James's classification, that any cause should be assigned for the disposition of one class of inflammations to be limited, and of another to spread; the two facts themselves being sufficient for the basis of the division.

There is much foundation for believing, that healthy inflammation is invariably a homogeneous process, obedient to ordained principles, and, in similar structures, similar situations, and in constitutions of equal strength, uniformly assuming the same features. If experience reveals to us, that *here* it is commonly productive of certain effects, and *there* it ordinarily produces different ones, the same unbounded source of wisdom communicates to the mind a knowledge, that there is some difference in the tone of the constitution, or in the structure or situation of the parts affected, assignable as the cause of this variety. A modern author (*Dr. Smith, in Med. Communications, vol.* 2) makes the nature of the exciting cause one principal ground of the specific distinctions in inflammation; and with good reason, when he takes into the account the action of morbid poisons, and the qualities of disease in general.

The doctrine also receives confirmation from what is observed in cases of burns and chilblains, where the inflammation is unquestionably attended with great peculiarity, requiring different treatment from that of common inflammation in general. But when the exciting cause is strictly mechanical, its violence and extent may cause differences in the degree and quantity of inflammation; but with respect to its quality, this must be accounted for by constitution, or other circumstances.

The attentive observation of experience, the only solid basis of all medical, as well as other knowledge, has informed the practitioner, that parts which, from their vicinity to the source of circulation, enjoy a vigorous circulation of blood through them, undergo inflammation more favourably, and resist disease better, than other parts, of similar structure, more remote from the heart. The lower extremities are more prone to inflammation, and disease in general, than parts about the chest; when inflamed, they are longer in getting well; and the circumstance of their being depending parts, which retards the return of blood through the veins, must also increase the backwardness of such parts in any salutary process. Healthy inflammation is of a pale red; when less healthy, it is of a darker colour; but in every constitution, the inflamed parts will partake more of the healthy red, the nearer they are to the source of the circulation.—(*Hunter.*)

Inflammation, when situated in highly organized and very vascular parts, is generally more disposed to take a prosperous course, and is more governable by art, than in parts of an opposite texture. The nearer also such vascular parts are to the heart, the greater will be their tendency to do well in inflammation.—(*Hunter.*) Hence, inflammation of the skin, cellular substance, muscles, &c. more frequently ends favourably, than the same affection of bones, tendons, fasciæ, ligaments, &c. It is also more manageable by surgery; for those parts of the body, which are not what anatomists term *vascular*, seem to possess inferior powers of life, and, consequently, when excited in a preternatural degree, frequently mortify.

But inflammation of vital parts, though they may be exceedingly vascular, cannot go on so favourably as in other parts of resembling structure, but of different functions; because the natural operations of universal health depend so much upon the sound condition of such organs.—(*Hunter.*) The truth of this observation is illustrated in gastritis, peripneumony, &c.

All new-formed parts, not originally entering into the fabric of the body, such as tumours, both of the encysted and sarcomatous kinds, excrescences, &c. cannot endure the disturbance of inflammation long, nor in a great degree. The vital powers of such parts are weak, and, when irritated by the presence of inflammation, these adventitious substances are sometimes removed by the lymphatics, but more commonly slough. This remark applies also to substances generated as substitutes for the original matter of the body; for instance, granulations and callus. The knowledge of this fact leads us to a rational principle of cure in the treatment of several surgical diseases. Do we not here perceive the cause, why large wens are occasionally dispersed by the application of urine, brine, and similar things, which are now in great repute, on this account, with almost every one out of the profession? How many verrucæ, wrongly suspected to originate from a syphilitic cause, are diminished and cured by a course of mercury! It is the stimulus of this mineral upon the whole system, that accomplishes the destruction of these adventitious substances—not its antivenereal quality. Topical stimulants would fulfil the same object, not only with greater expedition, but with no injury to the general health.

Inflammation, *cæteris paribus*, always proceeds more favourably in strong than in weak constitutions; for when there is much strength, there is little irritability. In weak constitutions, the operations of inflammation are backwards, notwithstanding the part in which it is seated may, comparatively speaking, possess considerable organization, and powers of life.

Healthy inflammation, wherever situated, is always most violent on that side of the point of inflammation which is next to the external surface of the body. When inflammation attacks the socket of a tooth, it does not take place on the inside of the alveolary process, but towards the cheek. When inflammation attacks the cellular substance surrounding the rectum, near the anus, the affection usually extends itself to the skin of the buttock, leaving the intestine perfectly sound, though in contact with the inflamed part.—(*Hunter.*)

We may observe the influence of this law in the diseases of the lachrymal sac and duct, in those of the frontal sinus, and antrum, and particularly in gunshot wounds. Suppose a ball were to pass into the thigh to within an inch of the opposite side of the limb, we should not find that inflammation would be excited

along the track of the ball, but on the side next the skin which had not been hurt. If a ball were to pass quite through a limb, and carry into the wound a piece of cloth, which lodged in the middle, equidistant from the two orifices, the skin immediately over the extraneous body would inflame, if the passage of the ball were superficial.—(*Hunter.*) Mr. Hunter compared this law with the principle by which vegetables approach the surface of the earth; but the solution of it was too arduous even for his strong genius and penetration.

We see three very remarkable effects follow inflammation; viz. adhesions of parts of the body to each other; the formation of pus, or suppuration; and ulceration, a process in which the lymphatics are more concerned than the blood-vessels. Hence, Mr. Hunter termed the different stages of inflammation, the *adhesive*, the *suppurative*, and the *ulcerative*.

All parts of the body are not equally liable to each of the preceding consequences.

In the cellular membrane, and in the circumscribed cavities, the adhesive stage takes place more readily than the others; suppuration may be said to follow next in order of frequency; and lastly, ulceration.

In internal canals, on the inner surfaces of the eyelids, nose, mouth, and trachea, in the air-cells of the lungs, in the œsophagus, stomach, intestines, pelvis of the kidney, ureters, bladder, urethra, and in all the ducts and outlets of the organs of secretion, being what are termed *mucous membranes*, the suppurative inflammation comes on more readily, than either the adhesive or the ulcerative stage. Adhesions, which originate from the slightest degree of inflammation in other situations and structures, can only be produced by a violent kind in the above-mentioned parts. Ulceration is more frequently met with upon mucous surfaces than adhesions. The cellular membrane appears to be much more susceptible of the adhesive inflammation than the adipose, and much more readily passes into the suppurative. Thus we see the cellular substance, connecting the muscles together, and the adipose membrane to the muscles, inflaming, suppurating, and the matter separating the muscles from their lateral connexions, and even the fat from the muscles, while the latter substance and the skin are only highly inflamed.—(*Hunter.*) But it must be allowed, that in situations where fat abounds, we very frequently meet with abscesses. This is so much the case, that fat has been accounted a more frequent nidus for collections of matter, than the cellular substance.—(*Bromfield.*) Abscesses are particularly liable to form in the neighbourhood of the anus, mamma, &c. With respect to the fat being highly inflamed, however, the expression is not strictly true. Fat has no vessels, principle of life, nor action of its own; consequently, we cannot suppose that it can itself either inflame or suppurate. We know that it is itself a secretion, and when an abscess forms in it, we understand, that the mode of action in the vessels, naturally destined to deposite fat, has been altered to that adapted to the formation of pus. When therefore the fat is said to be inflamed, it is only meant, that the membranous cells, in which it is contained, and by which it is secreted, are thus affected.

The deeply-situated parts of the body, more especially the vital ones, very readily admit of the adhesive stage of inflammation. The circumstance of deeply-seated parts not so readily taking on the suppurative stage of inflammation as the superficial ones do, is strikingly illustrated in cases of extraneous bodies, which, if deeply lodged, only produce the adhesive inflammation. By this process a cyst is formed, in which they lie without much inconvenience, and they may even gradually change their situation, without disturbing the parts through which they pass. But no sooner do these same bodies approach the skin, than abscesses immediately arise.

All inflammations, attended with disease, partake of some specific quality, from which simple inflammation is entirely free. When the constitution allows the true adhesive and suppurative stages to occur, it is to be regarded as the most healthy. Were it in an opposite state, we should see the very same irritation excite some other kind of inflammation, such as the erysipelatous, scrofulous, &c.—(*Hunter.*)

In specific inflammations, the position, structure, and distance of the part affected from the source of the circulation, as well as from the surface of the body, seem also to have as much influence as in cases of common inflammation. Upon this point, I feel conscious of being a little at variance with what Mr. Hunter has stated; but the undecided manner in which he expresses himself, not less than the following reflections, encourages me not to desert my own ideas. We see that venereal eruptions sooner make their appearance upon the chest and face than upon the extremities. No organized part can be deemed exempt from the attack of common inflammation; many appear to be totally insusceptible of the venereal. We know that scrofulous diseases of the superior extremities take a more favourable course, require amputation less frequently, and get well oftener, than those of the inferior limbs.—(*Ford.*) The venereal disease makes more rapid advances in the skin and throat, than in the bones and tendons; we often see it producing a specific inflammation, and an enlargement of the superficial parts of the tibia, ulna, clavicle, cranium, &c., while other bones, covered by a considerable quantity of flesh, are very rarely affected. Gouty inflammation is prone to invade the small joints; rheumatic, the large.

SYMPTOMS, NATURE, AND CAUSES OF INFLAMMATION.

Redness, swelling, heat, and pain, the four principal symptoms of the phlegmonous inflammation, have been accurately noticed by Celsus. *Notæ vero inflammationis sunt quatuor, rubor, et tumor, cum calore et dolore, lib.* 3, *cap.* 10. If we refer to any writer on this interesting part of surgery, we shall find the above symptoms enumerated as characterizing phlegmon. In short, this term is usually applied to a circumscribed tumour, attended with heat, redness, tension, and a throbbing pain. These are the first appearances observed in every case of phlegmon; and when they are slight, and the part affected is of no great extent, they have commonly very little, and sometimes no apparent, influence on the general system. But when they are more considerable, and the inflammation becomes extensive, a full, quick, and generally a hard pulse takes place, and the patient, at the same time, complains of universal heat, thirst, and other symptoms of fever. While the inflamed part becomes red, painful, and swelled, its functions are also impaired. The same degree of inflammation is said to produce more swelling in soft parts, and less in those of a harder structure.—(*Burns.*)

Though the redness, swelling, throbbing, tension, and other symptoms of phlegmonous inflammation, are less manifest when the affection is deeply situated, yet their existence is undoubted.

When persons die of peripneumony, or inflammation of the lungs, the air-cells of these organs are found crowded with a larger number of turgid blood-vessels, than in the healthy state, and, of course, the parts must appear preternaturally red. Coagulating lymph, and even blood, are extravasated in the substance of these viscera, which become heavier, and feel more solid.—(*Baillie.*)

The extravasation of coagulating lymph, which is one of the chief causes of the swelling, is also one of the most characteristic signs of phlegmonous inflammation.

Some writers (*Smith in Med. Commun. vol.* 2) restrict the seat of phlegmon to the cellular membrane; but this idea is erroneous. Had such authors duly discriminated the nature of common inflammation, they would have allowed, that this affection existed wherever the capillaries appeared to be more numerous and enlarged than in the natural state, accompanied with an effusion of coagulating lymph, whether upon the surface of a membrane or a bone, or in the interstices of the cellular substance, and attended with acute pain, and a throbbing pulsation in the part.

As Dr. Thomson has observed, the epithet *remote*, as applied to the *causes of inflammation*, does not appear to be happily chosen; for under this term are comprehended all those agents, events, and states, which contribute immediately as well as remotely, directly as well as indirectly, to the production of the affection.—(*Lectures on Inflammation, p.* 50.)

The remote causes of inflammation are infinite in number, but very easy of comprehension, because only divisible into two general classes. The first includes all such agents as operate by their stimulant or che

mical qualities; for instance, cantharides, heat, the action of concentrated acids, alkalies, metallic oxides, and metallic salts, acrid vapours, such as ammoniacal gas, the nitrous, sulphureous, muriatic gases, &c. alcohol, ether, and all acrid vegetable essential oils, animal poisons, and the whole of that class of substances known by the name of rubefacients.—(*Thomson on Inflammation*, p. 55.) The second class of causes are those which act mechanically, such as bruises, wounds, pressure, friction, &c.

Fevers often seem to become the remote causes of local inflammation. In other instances, inflammation appears to arise spontaneously, or, as I should rather say, without any perceptible exciting cause.

The principle, on which the application of cold to a part becomes the remote cause of inflammation, is not decidedly known. "No subject (says a distinguished professor) is more deserving of your study, than the effects which are produced in the human body by the operation of cold applied to its surface; but the subject is, at the same time, exceedingly extensive, complicated, and difficult. These effects differ according to the degree in which the cold is applied, the state of the system, the part of the body to which it is applied, and the mode of its application. So diversified, indeed, are these effects, that it requires no mean confidence in theoretical reasoning to believe, that the operation of cold in producing them is explicable upon any single general principle."—(See *Thomson on Inflammation*, p. 58.) And in the preceding page he observes: "The operation of cold upon the human body affords the best example which I can suggest to you, of the production of inflammation from the operation of a power acting upon a part at a distance from that in which the inflammation takes place. The instances formerly mentioned of inflammation of the throat, chest, or belly, from the application of cold to the feet, are daily occurrences in these climates, of which it is impossible for us, in the present state of our knowledge of the animal economy, to give any thing like a satisfactory explanation.

"In some instances, cold, or a diminution of temperature, seems to act more directly upon the parts with which it comes into contact. We have examples of this in the inflammation of the mucous membranes of the nose, fauces, trachea, and bronchiæ, from the inhalation of cold air; and in the production of rheumatic inflammation from the accidental exposure of some part or other of the body to cold. The application of cold, in the instances I have mentioned, seems to have somewhat of a directly exciting effect; and perhaps the same remark is still more applicable to the local effects of cold in the production of the inflammation accompanying the state which is usually denominated frost-bite. Touching a solid body, as a piece of metal, the temperature of which has been greatly reduced, produces a sensation like that of burning, and may be followed, like the application of fire, by a blister."—(*Op. cit.*)

Numerous opinions have been entertained respecting the *proximate cause of inflammation*; but almost every theory has been built upon the supposition of some kind of obstruction in the inflamed part.

While the circulation of the blood was unknown, and the hypothetical notions of the power of the liver, in preparing and sending forth this fluid, continued to prevail, physicians were so fully persuaded of the existence and influence of different humours and spirits, and so little did they know of the regular and constant motion of the blood, that they believed in the possibility of depositions and congestions of the blood, the bile, or lymph; and acknowledged these as the cause of inflammation. Their anatomists taught them, and their professors of physic supported the opinion, that the liver was the centre of the vascular system, from which the blood went forth by day to the extremities, and returned again by night. If then any peccant matter irritated the liver, the blood was sent out more forcibly; and if at the same time any part of the body were weakened, or otherwise disposed to receive a greater quantity of fluid than the rest, then a swelling was produced by the flow of humours to this place Fluxions, or flows of humour to a place, might happen either from weakness of the part, which allowed the humours to enter more abundantly, or from the place attracting the humours, in consequence of the application of heat or other agents. The peculiar nature of the swelling was supposed to depend upon the kind of humour. Blood produced the true phlegmon; bile, erysipelas, &c. An idea was also entertained, that the blood and humours might slowly stagnate in a part, from a want of expulsive power, and this affection was termed a *congestion*, while the expression *fluxion* or *defluxion* was used to denote any swelling arising from the sudden flow of humours from a distant part.—(*J. Burns' Dissertations on Inflammation.*)

From the theories of *fluxion* and *congestion*, which were quite incompatible with the laws of the circulation of the blood, we turn our attention to the doctrine of *obstruction*.

Boerhaave inculcated (*Aph.* 375, *et seq.*), that inflammation was caused by an obstruction to the free circulation of the blood in the minute vessels, and this obstruction, he supposed, might be caused by heat, diarrhœa, too copious flow of urine and sweat, or whatever could dissipate the thinner parts of the blood, and produce a thickness or viscidity of that fluid. When the lentor did not exist before the production of inflammation, he imagined that the larger globules of the blood passed into the small vessels, and thus plugged them up. This circumstance was termed an *error loci*. The obstruction, whether caused by *viscidity* or an *error loci*, was imagined to occasion a resistance to the circulation in the part affected; and hence, an increase of the flow of the blood in the other vessels, an irritation of the heart, and augmentation of the force or attraction of the blood in that part of the vessel which was behind the obstruction. This caused heat and pain, while the accumulation of the blood produced redness. Boerhaave also brought into the account an *acrimonious state of the fluids*, which rendered resolution out of the question, and gangrene likely to follow.—(*Aph.* 388.)

The viscidity of the blood cannot be admitted as the proximate cause of inflammation; because we have no proof that this state ever exists; or, granting that it did, it would not explain the phenomena. Were a viscidity to occur, it would exist in the whole mass of blood, would affect every part of the body alike, and could not be supposed to produce only a local disorder How, also, could such a lentor be produced by causes which bring on inflammation suddenly, without there being time for changes of the fluids to take place?

With regard to the doctrine of *error loci*, or of red globules going into vessels which did not formerly transmit them, the fact must be admitted, at the same time that the conclusion is denied. When the eye becomes inflamed, the tunica conjunctiva is seen with its vessels full of red blood, which in health is not the case: but this redness never appears until the inflammation has commenced, and must therefore be considered as an effect, not a cause. Nor can this *error loci* occasion any obstruction in these vessels; for if they be divided the blood flows freely, which shows that they are large enough to allow an easy circulation. —(*J. Burns.*)

Boerhaave's theory of obstruction was too circumscribed and too mechanical; it reduced all inflammations to one species: the only distinctions which could have arisen must have proceeded from the nature of the obstruction itself; and it was a doctrine that never could account for the action of many specific diseases and morbid poisons.—(*Hunter.*)

As for the supposition of the co-operation of an *acrimony of the fluids*, the proportion of the saline matter of the blood has never been proved to be greater in this than in any other state of the body.—(*Burns.*) Even were a general disorder of this kind to be admitted, no rational explanation of the proximate cause of local inflammation could be deduced from it.

The decided impossibility of giving a rational explanation of the immediate cause of inflammation by any supposed state of the blood alone, led pathologists to investigate how far a change in the blood-vessels themselves might account for the process. It belongs more properly to a physiological than a surgical work, to explain the various facts and experiments in support of the opinion, that the arterial tubes, and especially the capillaries, possess a high degree of vital contractility, whereby the motion of the fluids in them, the process of secretion, and other local phenomena, may be importantly affected, in a manner not at all explicable by reference only to the action and power of the heart. For such information, I would particularly

advise the reader to consult the publications of Dr. Wilson Philip and Dr. Hastings. According to the latter gentleman, the actual agency of the capillary vessels "is not only supported by such experiments as those related, it is also countenanced by an extensive series of phenomena presented during disease in the human subject. Of these may be mentioned irregular determinations of blood, the growth of tumours, increased pulsation of arteries leading to inflamed parts, of which the following is a well-marked example, the accuracy of which may be entirely relied upon. The carotids, when the person alluded to is in health, beat equally as to strength and frequency; but when he is attacked with inflammation in the right tonsil, to which he is particularly subject, and which proceeds sometimes so far as nearly to prevent deglutition, each pulsation of the artery gives a throbbing sensation on the right side of the head. On the application of the hand at this time to each carotid, the right is found to beat much stronger and fuller than the left. This diversity of action in these two arteries cannot arise from any impulse given by the blood to the heart: it must be derived from some modification of the contractile power of the artery." And Dr. Hastings expresses his belief in this explanation, notwithstanding Dr. C. H. Parry wishes to attribute to the remote influence of the heart some of the phenomena of local congestion and motion, and to show that the different states of vascular dilatation are still more conspicuously connected with the different degrees of action of the heart, and the consequent momentum of the blood, than with local circumstances; and that the proneness to local dilatation, or, as it is called, action, is a consequence of slowly succeeding but continued impulse.

The blood-vessels through every part of the system possess a considerable share of irritability, by which they contract, and propel forwards their contents. Hence, the blood, by the action of the vessels, receives a new impulse in the most minute tubes, and a well-regulated momentum is preserved in every part of its course. But of all parts of the sanguiferous system, the capillaries seem most eminently endowed with this faculty, and are least indebted to the presiding influence of the heart. Yet even in these vessels the action of the heart is of high importance in sustaining the healthy circulation, inasmuch as it gives the first impulse to the blood, and preserves the harmony of the sanguiferous system.

The vessels are endowed with this vital property, in order that each organ in the body may receive such a supply of blood as will enable it duly to exercise its functions. Hence, a healthy state of this property is absolutely necessary for the preservation of the animal functions; for if the vital contraction of the blood-vessels be either increased or diminished, irregular distribution of the blood inevitably follows, and from this source numerous diseases arise, and none more frequently than inflammation. However, though these sentiments, delivered by Dr. Hastings, may be generally correct, I am not prepared to join in the opinion, that inflammation is ever produced simply by an inequality in the distribution of the blood; a statement which this gentleman probably does not mean to make himself, as he confesses, that some of the phenomena of this disease depend upon sympathy between the sanguiferous and nervous systems.—(See *Hastings on Inflammation of the Mucous Membrane of the Lungs, &c. p.* 32, 64, 65, 8*vo. Lond.* 1820; *and C. H. Parry, Additional Experiments on the Arteries, &c. p.* 112, 114; *also Whytt on the Motion of the Fluids in the small Vessels*; *Verschuir de Arteriarum et Venarum Vi irritabili*; *Zimmerman de Irritabilitate, p.* 24; *Hunter on the Blood, &c.*)

Dr. Cullen attributed the proximate cause of inflammation to a "spasm of the extreme arteries supporting an increased action in the course of them." This theory only differs from that of Boerhaave in the cause which is assigned for the obstruction. Dr. Cullen conceived, however, that some causes of inequality in the distribution of the blood might throw an unusual quantity of it into particular vessels, to which it must necessarily prove a stimulus; and, that in order to relieve the congestion, the vis medicatrix naturæ increases still more the action of the vessels; which, as in all other febrile diseases, it effects, by the formation of a spasm on their extremities. "A spasm of the extreme arteries, supporting an increased action in the course of them, may, therefore, be considered as the proximate cause of inflammation; at least, in all cases not arising from direct stimuli applied; and even in this case the stimuli may be supposed to produce a spasm of the extreme vessels."—(*Cullen.*)

The inconsistencies in Cullen's theory are very glaring. The congestion, or accumulation of blood, which is only an effect or consequence of inflammation, is set down as the cause of the spasm of the vessels, to which spasmodic constriction Cullen, strangely enough, assigns the name of proximate cause. The spasmodic contraction of the extremities of the vessels, instead of propelling the accumulated quantity of blood, would render the passage of the blood from the arterial into the venous system still more difficult.—(*Burns.*)

We shall now notice the celebrated and very original opinions promulgated on this subject by John Hunter. According to him, inflammation is to be considered only as a disturbed state of the parts, which requires a new but salutary mode of action to restore them to that state, wherein a natural mode of action alone is necessary. From such a view of the subject, therefore, inflammation in itself is not to be considered as a disease, but as a salutary operation, consequent either to some violence or some disease. Elsewhere, the author remarks, the act of inflammation is to be considered as *an increased action of the vessels, which, at first, consists simply in an increase or distention beyond their natural size. This increase seems to depend upon a diminution of the muscular power of the vessels*, at the same time that the elastic power of the artery must be dilated in the same proportion. *This is, therefore, something more than simply a common relaxation:* we must suppose it an action in the parts to produce an increase of size for particular purposes, and this Mr. Hunter would call *an act of dilatation.* The whole is to be considered as a necessary operation of nature. Owing to this dilatation, *there is a greater quantity of blood circulating in the part*, which is according to the common rules of the animal economy; for, whenever a part has more to do than simply to support itself, the blood is there collected in larger quantity. The swelling is produced by an extravasation of coagulable lymph, with some serum; but this lymph differs from the common lymph, in consequence of passing through inflamed vessels. It is this lymph which becomes the uniting medium of inflamed parts; vessels shoot into it; and it has even the power of becoming vascular itself. The pain proceeds from spasm. The redness is produced either by the arteries being more dilated than the veins, or because the blood is not changed in the veins. "As the vessels become larger, and the part becomes more of the colour of blood, it is to be supposed there is more blood in the part; and as the true inflammatory colour is scarlet, or that colour which the blood *has* when in the arteries, one would from hence conclude, either that the arteries were principally dilated, or, at least, if the veins are equally distended, that the blood undergoes no change in such inflammation in its passage from the arteries into the veins, which I think (says Mr. Hunter) most probably the case; and *this may arise from the quickness of its passage through those vessels.* When a part cannot be restored to health, after injury, by inflammation alone or by adhesion, then suppuration, as a preparatory step to the formation of granulations, and the consequent restoration of the part, takes place. The vessels are nearly in the same state as in inflammation; but they are more quiescent, and have acquired a new mode of action."—(*Hunter.*)

With respect to Mr. Hunter's theory, which has deservedly had vast influence in regulating the judgment of professional men in this country on the nature of the process called inflammation, it cannot be received in the present state of knowledge without some limitation. The hypothesis, that the blood-vessels possess an active power of dilatation, independently of their elasticity, as Dr. Hastings observes, must as yet be regarded as devoid of proof, and therefore should not be assumed as a basis on which any theory of inflammation can be founded.—(*On Inflammation of the Mucous Membrane of the Lungs, &c. p.* 70.) And, as another intelligent writer remarks, how different would have been Mr. Hunter's inferences, if, instead of trusting to the unassisted eye, he had viewed the inflamed vessels through the microscope! He would then have

seen the blood moving, and found, that "*instead of its passage being quickened in the inflamed vessels, it is uniformly rendered slower in proportion to the degree of inflammation, and in the most inflamed parts stands still altogether.*"—(*On the Vital Functions, p.* 208, *ed.* 2.) And in another part of his writings, Dr. Philip has endeavoured to prove, from several facts respecting the colour of the blood, that, *within certain limits, the accumulation of this fluid in the debilitated vessels of the inflamed part necessarily causes the blood to retain the florid colour.*—(*On Fevers, part* 2, *Introd.*)

In modern times, the vague but convenient expression, *increased action of the vessels*, has been very generally used as an adequate explanation of the proximate cause of inflammation. The doctrine, it is said, derives support from a review of the several exciting causes of the affection, which, being in general of an irritating nature, must, when applied to any living or sensible parts, occasion such increased action of the vessels; while the method of cure also tends to confirm the opinion. But before one can judge whether this doctrine is correct, and supported by facts and observation, it is necessary to understand precisely what is implied by increased action of vessels? for it is not every affection of the vessels, capable of being thus denominated, which will of itself constitute inflammation. In gestation, the arteries of the womb are enlarged, and a greater quantity of blood is sent into them; yet this organ is not inflamed. The carotids are in a similar state during the growth of the stag's horn; but no inflammation exists. If then the proximate cause of inflammation is to be called an increased action of the vessels, we must first be informed, not only what is meant by the term, but what particular vessels are spoken of, whether the arterial trunks, branches, or capillaries. Because, if the phrase is intended to signify increased alternate expansions and contractions of all the arteries of the inflamed part, it is an hypothesis entirely destitute of foundation. If it be meant to denote an increased velocity of the motion of the blood in the part affected, the doctrine is rather contradicted than confirmed by the latest and most carefully instituted microscopical experiments. But if the expression only refers to the dilated state of the capillaries, the throbbing of the arteries leading to the seat of inflammation, the effusion of lymph, &c., less fault can be found with the language, though yet requiring much farther explanation ere it can communicate any very precise information.

"There are (says a learned professor) two hypotheses which at present divide the opinions of pathologists, respecting the state of the capillary vessels affected with inflammation. According to the first of these hypotheses, the inflamed vessels are in a state of increased action; according to the second, they act with less force than the trunks from which they are derived."—(See *Thomson on Inflammation, p.* 64.)

The first of these opinions, according to Dr. Thomson, was suggested by the views which Stahl took of the animal economy, and his ideas respecting the tonic or vital action of the capillary vessels. The doctrine, however, was more particularly insisted upon by his disciples and followers, especially De Gorter, who, in one place, expressly states, "that the proximate cause of inflammation consists in an increased vital action of some particular artery or arteries, by which the blood is propelled with greater force than usual into the communicating, lymphatic, and colourless vessels."—(See his *Compendium Medicinæ* and *Chirurgia Repurgata.*)

The doctrine which supposes the action of the inflamed vessels to be diminished, or to be proportionably less than that of the trunk or trunks from which they are derived, was, as far as Dr. Thomson can learn, first stated by Vacca, an Italian physician, in a small treatise on inflammation, published at Florence in 1765, entitled, "*Liber de Inflammationis Morbosæ, quæ in humano corpore fit Naturâ, Causis, Effectibus, et Curatione.*"

For an account of the arguments with which Vacca supports his hypothesis, my limits oblige me to refer to the work of Dr. Thomson.—(*P.* 68, *&c.*)

As this gentleman has observed, there are certain points in which the two doctrines agree, as well as in which they differ

"The advocates for each hypothesis agree in admitting, 1st, that inflammation has its seat in the capillary vessels; and, 2dly, that the redness in inflammation is owing to an unusual quantity of blood in the vessels of the inflamed part, and consequently that the capillary arteries are much dilated during the state of inflammation. The contractions of these vessels, indeed, it has been said, are increased also in a ratio proportional to the dilatations; but this is an assertion which has not yet been proved, either in the way of experiment or of observation.

"The sense of throbbing, which the advocates for the hypothesis of increased capillary action regard as the strongest proof of that action, Mr. Allen is disposed to attribute to the difficulty which the blood meets with in passing from the trunk into the capillary branches. This sensation of throbbing, and appearance of increased action, may be produced in an instant, by applying a ligature to an uninflamed finger, so as to obstruct the motion of the blood through its point. Besides, this throbbing or pulsatory motion can afford us no criterion by which to judge of the force with which the artery contracts, for it is produced in the dilatation of the artery, and by a power foreign to the artery itself."—(*Thomson on Inflammation, p.* 73.)

Dr. Wilson Philip, many years ago, endeavoured to ascertain, by means of the microscope, the state of the vessels in the various stages of inflammation, both in the *warm* and *cold* blooded animal. I have put the epithet warm in Italics, because it has been observed by my friend, Mr. James, that "analogies between the higher and lower orders of animals, the chief subjects of these experiments, cannot be deemed conclusive" (*On some of the General Principles of Inflammation, p.* 29, *8vo. Lond.* 1821), as if it had escaped attention, that many of the experiments were really made on the more perfect animals. From the valuable observations to which I here allude (see *Philip on Febrile Diseases, part* 2, *Introd.*), it appears, that the state of the smaller vessels in an inflamed part is that of preternatural distention and debility. As for the larger vessels, whose state may be ascertained without the aid of the microscope, "they do not undergo a similar distention, and the increased pulsation of the arteries sufficiently evinces their increased action. In inflammatory affections of the jaw and the head, for example, a greatly increased action of the maxillary and temporal arteries is readily perceived by the finger. It is to be observed, however, that although inflammation, as was evident from the foregoing experiments, begins in the capillaries, if it continues, the circulation in the smallest vessels becoming very languid, those immediately preceding them in the course of the circulation begin to be distended, and consequently debilitated." Dr. Philip adds, that such distention and debility of the vessels which immediately precede the capillaries, cannot go far, because when the former lose their power, the circulation in the latter is not supported, and gangrene soon ensues. "*In short* (says Dr. Philip), *inflammation seems to consist in the debility of the capillaries, followed by an increased action of the larger arteries,*" and is terminated by resolution, when the capillaries are so far excited, and the larger arteries so far weakened, by the preternatural action of the latter, that the power of the capillaries is again in due proportion to the *vis à tergo.*

"Thus far (says Dr. Philip) I cannot help thinking the nature of inflammation appears sufficiently evident. The motion of the blood is retarded in the capillaries, in consequence of the debility induced in them; an unusual obstacle is thus opposed to its motion in the arteries preceding them in the course of the circulation; which are thus excited to increased action. Several difficulties, however, remain, on which the experiments just related throw no light. Why does a failure of power, of small extent in the capillaries of a vital part, strongly excite not only the larger arteries of the part affected, but those of the whole system; while a more extensive debility of the capillaries of an external part excites less increased action in the larger arteries of that part, and often none at all in those of the system in general? Why does inflammation often move suddenly from one part to another, when we see no cause, either increasing the action of the capillaries of the inflamed part, or weakening those of the part now affected? Why does inflammation often arise in parts only sympathetically affected, and consequently far removed from the offending cause? Why is inflammation often as apt to

spread to neighbouring parts, between which and the part first affected there is no direct communication of vessels, as to parts in continuation with that part?

"These phenomena, it is evident (says Dr. Philip), are referable to the agency of the nervous system, and seem readily explained by the experiments, which prove, that the effects of both stimuli and sedatives, acting through this system, are felt by the vessels, and that independently of the intervention of any effect produced on the heart.—(*Exp.* 27, 28.) Thus, the irritation of the nerves of the inflamed part may excite the larger arteries of this part, or of distant parts, or of the whole sanguiferous system. It will of course be most apt to do so where the irritation excited by the inflammation is greatest, and consequently in the more important vital parts. It cannot appear surprising, that inflammation should suddenly cease in one part and attack another, when we know that the nerves are capable of exciting to due action the capillaries of the one part, and in the other of impairing the vigour of those which have not suffered. In the same way, we account for parts only sympathetically affected becoming inflamed, and for inflammation readily spreading to neighbouring parts, which always sympathize, although there is no direct communication between them, either of vessels or nerves."—(*On the Vital Functions, p.* 279, *&c. ed.* 2.)

Respecting the inference made by Dr. Philip from his experiments, that the circulation is slower in inflamed than uninflamed arteries; Dr. J. Thomson conceives, that its truth "is not necessary to the establishment of Mr. Allen's hypothesis; and from a number of experiments which I have at different times made upon frogs, I am inclined to believe, *that a diminished velocity of the blood in the capillary branches, is by no means a necessary, constant, nor even the most common effect of incipient and moderate degrees of inflammation.*"—(*P.* 75.)

In order to reconcile this difference in the statements made by the only two writers who have examined this subject by experiment, Dr. Hastings repeated their mode of investigation with the aid of the microscope. His conclusions are, "that certain stimuli, applied to living parts, produce an increased velocity of the blood's motion, and a contraction of the blood-vessels. During this state of excitement, the part affected is so far from giving any thing like the appearances of inflammation, that the size of the vessels is diminished, and the part paler. But if the stimulus be long continued, or increased in power, the small vessels, which in the natural state admit only of one series of globules, become so dilated as to allow an accumulation of a much less fluid and redder blood in them, which loses its globular appearance, and *moves much more slowly* than that which previously passed through the vessels. The part now appears inflamed. If the stimulus be removed, the vessels do not soon regain their original state; time is necessary to allow them to recover their contractile power, so as to prevent the impetus, with which the blood is propelled by the heart and larger arteries, from keeping up the dilated state of the capillaries. Here then we are obliged to admit, with Boerhaave, that there is an error loci; for a denser and redder blood passes into small vessels, which before carried much more fluid contents: but the error loci does not cause the inflammation, but results from the previously weakened state of the capillaries. In this manner the blood may occasionally be extravasated in inflammation, without any actual rupture of a vessel, for the exhalents may be so weakened and dilated as to allow globules to pass through them.

"If the stimulus which produces the inflammation be of a very acrid nature, debility of the vessels is frequently induced without any previous excitement. The blood in all the smaller vessels becomes very red, circulates very slowly, and in some vessels stagnates.

"The application of a stimulus, different from that which produced inflammation, will sometimes bring on resolution. When this occurs, the dilated vessels contract; they no longer contain a red, dense, homogeneous fluid, but again receive blood, consisting of small, nearly colourless globules, which float in a colourless fluid; and the motion of these globules at length becomes as quick as before the inflammation took place. If, however, the inflammation proceed, the blood becomes nearly stagnant; it continues very red, and the vessels are much dilated.

"When this high degree of inflammation is not relieved, sphacelus ensues. The part then feels softer to the finger, and gives way with less force. The vessels are much dilated, the blood does not move, it loses its red colour, and becomes of a yellowish brown hue. The separation of the dead from the living part takes place soon after this change in the colour of the blood.

"While the ulceration produced by this separation of the dead from the living part of the web is healing, the capillary vessels, distributed on the ulcerated surface, and the contiguous parts, are much distended with arterial red blood, which is moved very slowly When the ulceration is healed, the vessels become contracted, and circulate the fluid with the same degree of velocity as before the inflammation was excited.

"With respect to the seat of inflammation, it may be observed, that *the capillaries are first affected;* but even the small arteries of the web are also occasionally distended."—(*Hastings on Inflammation of the Mucous Membrane of the Lungs, &c. p.* 90—92.)

With respect to the doctrine espoused by some pathologists, that the smaller branches of veins are the exclusive seat of inflammation, the same author observes, that the microscope shows us that the most minute arterial branches, though far less numerous, are equally affected with weakness and distention. But, as Mr. Lawrence has remarked on this part of the subject, how can we tell whether the arteries or the veins are exclusively affected? Is the distinction even practicable? If we trace the vessels of a part, we soon come to the points at which we can no longer distinguish between arteries and veins; we find a minute net-work of vascular ramifications, which cannot be unravelled or distinguished.—(See *Lancet, vol.* 9, *p.* 339.)

In the course of Dr. Hastings's inquiry, it is proved that the healthy circulation of the blood essentially depends upon a due degree of action in the vessels throughout the system; that the application of stimuli, while it increases the action of the vessels, produces none of the symptoms of inflammation. When, however, the excessive action of these stimuli has impaired the excitability of the small vessels, the phenomena of inflammation are fully manifested; and when their excitability is restored, the inflammation subsides. It may be logically inferred, therefore, says this writer, that *inflammation consists in a weakened action of the capillaries, by which the equilibrium between the larger and smaller vessels is destroyed, and the latter become distended.* And with respect to the conclusion drawn by Dr. Thomson from his experiments, that inflammation, in moderate degrees, consists in an increased action of the vessels, Dr. Hastings argues, that the writer's belief in the excitement of the capillaries, in some cases of inflammation, arises from his having denominated that a state of inflammation which ought not to be so called. "The application of the salt (says Dr. Thomson) produced an increased velocity in the dilated larger and smaller arteries and capillary vessels, to which it is more immediately applied. In nine experiments, the phenomena of which I have minutely recorded, the application of the salt was not only followed by a bright red colour, visible to the naked eye, and a sensible enlargement of the arterial and venous branches, but with an increased rapidity of circulation in the capillary vessels; the globules becoming less distinct than before the application of the salt, and obviously less distinct, from the rapidity of their motion, than the globules in the capillary vessels in the uninflamed part of the web in the same animal. *The repeated application, however, of the salt to the same vessels, was always sooner or later followed by retarded capillary circulation, or even by complete stagnation.*—(See *Thomson's Lectures, p.* 68.) The results of other experiments made by this gentleman, and which coincide with the sentiments of Dr. W. Philip and Dr. Hastings, need not here be cited.

Now, with regard to those experiments which seemed to Doctor Thomson to justify the inference that moderate degrees of inflammation may be attended with an increased velocity of the blood in the inflamed vessels, Dr. Hastings, as I have already said, objects, that the appearances seen while such velocity of the circulation presented itself in the vessels affected, ought not to have been denominated inflammation; because "it constantly happened in his own experiments, that

when inflammation commenced, no globules could be seen even in the blood of the affected vessels. It was universally converted into a bright red homogeneous fluid. So that *globules could never be seen in the capillaries of a really inflamed part, much less moving with great velocity.*" He argues, that the state alluded to by Dr. Thomson, is only that temporary excitement of the capillaries, generally preceding their debility, which is inseparable from inflammation.—(See *Hastings on Inflammation, &c. p.* 98—101.)

Of course, such writers as believe that the blood in the capillaries is not propelled by these vessels themselves, but by the impulse received from the heart, cannot assent to the foregoing view, in which the proximate cause of the inflammation is ascribed to debility of those vessels. Dr. Parry argues, that the theory which represents this process as consisting in an increased momentum of the blood in the part affected, is not invalidated, were it even proved, according to the opinion of Dr. Philip, that the velocity of the blood in the vessels of an inflamed part is diminished, unless it be also proved that the velocity is diminished in a greater proportion than the quantity is increased.—(*Elements of Pathology, vol.* 1, *p.* 84.) As far, however, as I can judge, the arguments are in favour of Dr. Philip's view of the subject; for with respect to quantity making up for loss of velocity, if the supposition were to be adopted, surely it could not be retained after the inflammation has arrived at that state, in which the fluid in the capillaries is seen with the microscope to be nearly or quite stagnant. It must be confessed at the same time, that the question about the proximate cause of inflammation is still a topic of endless controversy, into which I consider it perfectly absurd to enter any farther without prosecuting the inquiry by experiments. In one sense both Dr. Philip and Dr. Hastings admit that an increased action of the vessels may exist in inflammation; but then this excitement or increased action is not in the capillaries, but the larger arteries: and Dr. Philip even suggests, that the presence or absence of such excitement may make the difference between acute and chronic inflammation. The considerations in support of the side of the question to which I do not myself incline, may be found in the writings of Dr. Parry, Dr. C. H. Parry, and Mr. James. From this remark I would not have it inferred that I am at all convinced of the propriety of referring the proximate cause of inflammation to *debility* of the capillaries, though the retarded circulation in them, like their dilatation, is now a fact placed out of all doubt. The points, however, on which I should not assent to Dr. Philip's doctrine, will be best understood, when the treatment is considered. In the work of Mr. James may be perused a good summary of Bichat's doctrine, which I would willingly annex if the subject were intelligible without an explanation of some physiological opinions, for which I have not room.

Redness.—This is manifestly owing to the increased quantity of blood in the inflamed part. More blood must necessarily be contained there, because the vessels which previously conveyed this fluid are preternaturally distended, and the small vessels, which naturally contained only lymph, are now so enlarged as to be capable of receiving red blood. "I froze (says Mr. Hunter) the ear of a rabbit, and thawed it again; this occasioned a considerable inflammation, an increased heat, and thickening of the part. This rabbit was killed when the ear was in the height of inflammation, and the head being injected, the two ears were removed and dried. The uninflamed ear dried clear and transparent, the vessels were distinctly seen ramifying through its substance; but the inflamed ear dried thicker and more opaque, and its arteries were considerably larger."

Many have supposed that the redness of common inflammation is partly occasioned by the generation of new vessels. This doctrine, however, seems very questionable. When coagulated lymph is extravasated upon the surface of a wound, or an inflamed membrane, unquestionably it often becomes vascular, in other words, furnished with new vessels. But in the extravasated lymph of a phlegmonous tumour, we have no evidence that there is any formation of new vessels. Were the lymph to be rendered organized and vascular, the swelling and redness would probably be more permanent, and at least not admit so easily of resolution. When adhesions are formed between two inflamed surfaces, the organized substance forming the connexion lives after the subsidence of the inflammation, and is a permanent effect. In the experiments detailed by Dr. Hastings, when the inflammation began and terminated without any lesion of the part affected, new vessels were never formed.—(*On Inflammation, &c. p.* 93.) At the same time it must be confessed, that great obscurity prevails in this very difficult part of the subject; for when suppuration happens in a phlegmonous tumour, the cavity is lined by a kind of cyst, or membranous layer of lymph, which is unquestionably furnished both with secreting vessels and absorbents; for, otherwise, how could the continued secretion of pus, or its occasional sudden disappearance, be at all explicable? It was probably the enlargement of the small vessels, and the circumstance of their being filled with red blood, that led to the theory of new vessels being usually formed in inflammation. It has, however, been justly observed, that the supposition easily admits of refutation; for heat and many other causes of inflammation operate so quickly, that there can be no time for the formation of any new vessels; and yet the redness is as great, and the inflammation as perfect, in a minute, as in an hour or a day after the application of the exciting cause.—(*Burns.*) Mr. Hunter, it is well known, believed that a coagulum or layer of lymph might produce vessels within itself.—(*On the Blood, p.* 92, *&c.*) Others, however, distrust this hypothesis, and incline to the opinion, which refers the derivation of vessels for the organization of deposites to parent branches.—(*Travers, Synopsis of Diseases of the Eye, p.* 113.) The latter sentiment is corroborated by the appearances noticed by Dr. Hastings in his experiments, who describes the small vessels first seen in the lymph upon the surface of a wound, as even then communicating with the inflamed capillaries.—(*On Inflammation, p.* 94.) Another reason assigned for the redness of inflammation is, that the blood, after it has become venous, retains, more or less, its bright scarlet colour.—(*Hunter.*) And, in some late very carefully conducted experiments, it was remarked, that the weakened action of the smaller vessel was always accompanied with an alteration in the appearance of the blood. In the natural state of this fluid, globules can be distinctly seen; but after inflammation has commenced, the globular structure disappears, the blood becomes redder, and the most minute capillaries are distended with it.—(*Hastings on Inflammation, &c. p.* 95.)

Swelling.—This effect arises from several causes: 1 The increased quantity of blood in the vessels. 2. The effusion of coagulating lymph, and serum, and deposition of new matter. 3. The interruption of absorption particularly noticed by Soemmering.—(*De Morb. Vas. Absorb.*)

Pain.—This is observed to be the greatest during the diastole of the arteries. The affection is probably owing to the unnatural state of the nerves, and not to mere distention, as many have asserted. Were the latter cause a real one, the pain would always be proportioned to it.

"Parts, which in the sound state have little or no sensibility (as Dr. Thomson remarks), become exquisitely sensible in the inflamed. That this is the case with tendon, ligament, cartilage, bone, and membrane, seems to be fully established by Dr. Whytt in the very instructive controversy carried on between him and Haller respecting the sensibility and irritability of the different parts of man and other animals."—(*Lectures on Inflammation, p.* 45.)

Heat.—The heat or real increase of temperature in an inflamed part, when judged of by the thermometer, is generally much less than might be supposed from the patient's sensations. It is said never to exceed the heat of the blood at the heart. This in health is usually about 100° Fahrenheit's thermometer; but sometimes in diseases it rises to 106° or even 107°. Mr. Hunter artificially excited inflammation in the chest of a dog, and in the abdomen, rectum, and vagina of an ass, without being able to discover any obvious rise of temperature in these parts. In a patient, however, on whom he operated for hydrocele, the thermometer, introduced into the tunica vaginalis, and kept for some time close to the side of the testicle, was only 92°; but rose the following day, when inflammation had come on, to 98½°. As Dr. Hastings observes, the advocates for

excited action of the vessels in an inflamed part have thought, that the increase of temperature favours their hypothesis, and have called to their aid the ingenious calculations of Dr. Crawford. They have even gone so far as to say what state of the arteries enables the blood to give out most caloric. They tell us, that, in consequence of excitement of the vessels, more blood is transmitted into the minute arteries; the capacity of a greater quantity of this fluid for heat is of course diminished, and more caloric is evolved in the inflamed part.—(*Hastings on Inflammation, p.* 110.) Yet this theory, besides involving the contradicted hypothesis of an increased and accelerated flow of blood through the vessels of the inflamed part, cannot be reconciled to various other considerations. "Daily experience convinces us (says the above writer), that the temperature is not always proportional to the velocity of the circulation. In revers, the author has several times ascertained, with the thermometer, that the heat was 101°, when the pulse beat only 45 times in a minute. In hydrocephalus, with the pulse from 60 to 70, the heat is often above the degree it reaches in health. In these cases, according to the theory of Dr. Crawford, the heat should rather be under than above the natural standard."—(*Op. cit. p.* 112.) And, as another judicious writer has noticed, although the former mode of explaining the production of animal heat has been held adequate to account for the phenomena by such philosophers as Black, Crawford, Lavoisier, and Place, the evidence on which it rests is not so clear as to have commanded universal assent, or entirely set aside objections. It has indeed been generally allowed, that respiration and the changes it produces in the air and animal fluids, are essential conditions of the evolution of caloric in animals; but it has been thought that there are other circumstances, hitherto, perhaps, not well understood, which influence the phenomena. In external appearance, the blood is the same in all the vessels of the fœtus: is this any proof that its temperature is owing to the conversion of oxygen gas into carbonic acid? Is the uniformity of temperature in the higher animals, under varying states of respiration and circulation, and the consumption of various quantities of oxygen, whether in the same or different individuals, consistent with the theory? And can local variations of temperature be explained by it?—(*Rees's Cyclopædia, art. Respiration.*) Doubts must also spring from the recollection of the discordance of the experiments related by Dr. Crawford, Dr. John Davy, De la Roche, and Berard. In fact, the determinations of the specific heats of oxygen gas and carbonic acid by the two latter experimenters are conceived to be very much against the probability of Dr. Crawford's theory. Other stronger grounds for skepticism in this subject are the results of Mr. Brodie's investigations. Having pithed or decapitated animals, he kept up artificial respiration, and thus maintained their circulation. The blood continued to be changed in the lungs from venous to arterial, and from arterial to venous, in the general circulation. The respective colours of the two kinds of blood could not be distinguished from those which they exhibit in living and healthy animals. Yet the temperature of an animal thus heated, sunk faster than that of another animal simply killed and left to itself; and the former was supposed to be more quickly cooled by the air conveyed into its chest. Other experiments, detailed by Mr. Brodie, tend to prove that the oxygen of the air, employed in artificial respiration, underwent its usual conversion into carbonic acid. A living rabbit formed 50 or 56 cubic inches of carbonic acid in an hour. A decapitated animal, in whom artificial respiration was kept up, emitted 40 to 48 inches in the same time. The thermometer in the rectum of the latter had fallen from 97 to 90, while, in another rabbit left to itself, but similarly treated in all other respects, it had fallen only to 91. In a rabbit poisoned with woorara, or the essential oil of bitter almonds, not decapitated, and in which artificial breathing was kept up, 51 cubic inches of carbonic acid were emitted in an hour. The thermometer in the rectum had sunk to 91 in 30 minutes, while it stood at 92 in another animal, treated exactly in the same way, with the omission of the artificial breathing. From these experiments, Mr. Brodie infers, "that, in an animal in which the brain has ceased to exercise its functions, although respiration continues to be performed, and the circulation of the blood is kept up to the natural standard, although the usual changes in the sensible qualities of the blood take place in the two capillary systems, and the same quantity of carbonic acid is formed as under ordinary circumstances; no heat is generated, and (in consequence of the cold air thrown into the lungs) the animal cools more rapidly than one which is actually dead."—(See *Phil. Trans. for* 1811, *p.* 36, *and for* 1812, *p.* 378.) It appears certain, therefore, that the generation of animal heat, either in an inflamed or an uninflamed part, can never be satisfactorily explained by any reference merely to chemical principles, and that the process is essentially connected with, and influenced by, the state of the functions of the brain and nervous system, and no doubt also by the principle of life itself. At the same time, I think that any hypothesis suggested without due reference to the connexion which respiration has with this curious and interesting process, will never be established. Neither would I venture so far as Dr. Philip, who believes that animal heat is evolved by the same means by which the formation of the secreted fluids is effected, viz. the action of nervous influence on the blood, and that the production of such heat is to be regarded as a secretion.—(*On the Vital Functions, p.* 169.) However, the influence of the nervous system over this process must be allowed to be very great, and may afford a more probable explanation of the cause of the local change of temperature in inflammation than Dr. Crawford's theory, combined with the doctrine of increased action, and an accelerated circulation in the vessels of the part affected.

Buffy coat.—The blood, when taken out of the living vessels, spontaneously separates into two distinct parts, the serum and the crassamentum. The last is a compound substance, consisting chiefly of coagulating lymph and red globules, the most heavy ingredients in the blood. Blood, taken away from persons affected with inflammation, is longer in coagulating, and coagulates more firmly, than in other instances. Hence, the red globules, not being so soon entangled in the lymph, descend, by their gravity, more deeply from its surface, which being more or less divested of the red colouring matter, is from its appearance termed the *buffy coat*, or *inflammatory crust.* The firmer and more compact coagulation of the lymph compresses out an unusual quantity of serum from it, and the surface of the sizy blood is often formed into a hollow, the edges being drawn inwards.—(*Hunter.*) In some cases these changes in the blood are deemed a more unequivocal proof of the existence of inflammation, than the state of the pulse itself. They are, however, only a criterion of some unusual operation going on in the system; for the blood taken from pregnant women is always found to present the same phenomena. In peritonæal inflammation, the patient sometimes seems to be in the most feeble state, and the pulse, abstractedly considered, would rather induce the practitioner to employ tonics and stimulants than evacuations; but should the continuance or exasperation of the disorder, or any other reason, lead him to use the lancet, then the *buffy coat*, and the *concave surface*, of the blood, materially obviate any doubt of the existence of inflammation. Surgeons should never forget, however, that in a few anomalous constitutions, the blood, when drawn, always exhibits the above peculiarities.

Terminations.—Inflammation is said to have three different terminations; or, in more correct language, we may say, that, after this process has continued a certain time, it either subsides entirely, induces a disposition in the vessels to form pus, or completely destroys the vitality of the part.

When the inflammation is to end in the first manner, which is the most favourable, the pain becomes less, the swelling subsides, the fever, and every other symptom, gradually abate, till at last the part is wholly restored to its natural size and colour. There is no formation of pus, nor any permanent injury of structure; and, if Dr. Philip's theory of inflammation be correct, the debilitated capillaries are excited to due action by the increased action of the larger arteries.—(*On the Vital Functions, p.* 298.) This termination of inflammation is termed by surgeons *resolution.* It is fortunately the most common, as well as the most desirable, manner in which the affection ends.

If, however, notwithstanding the application of the usual remedies, the several symptoms of heat, pain, and redness, instead of diminishing, rather increase; if the

febrile symptoms are likewise augmented, and the tumour gradually acquires a larger size, turns soft, somewhat prominent in the middle, or towards its most depending part; if it should next acquire a clear shining appearance, and become less painful, the different symptoms of fever being at the same time diminished, and a fluctuation perceptible in the tumour, the inflammation has ended in *suppuration*.

The worst but, happily, the least frequent consequence of common inflammation, is the death or *mortification* of the part affected. In the microscopical experiments of Dr. Hastings, it was observed, that, on the approach of gangrene, the blood entirely loses its red colour, and acquires a yellowish-brown tinge.—(*On Inflammation*, *p.* 97.) The part which was of a bright red becomes of a livid hue; small vesicles, filled with a thin fetid serum, arise on its surface, and air is plainly felt within the cellular membrane. The pain is indeed diminished, but the pulse sinks, while the tumour is gradually changed into a black fibrous mass.

These are the three common terminations of inflammation. In books, scirrhus is sometimes enumerated as one of the terminations of inflammation. The best modern surgeons, however, do not regard scirrhus as one of the usual effects of ordinary inflammation: "the term scirrhus, as used by the older medical writers, is extremely indefinite, having been sometimes used to express every kind of induration, which remained after an attack of inflammation, as well as the morbid incipient state of parts about to become affected with cancer. Surgeons now usually limit the use of the term to the last of these significations."—(*Thomson on Inflammation*, *p.* 126.)

Common inflammation, particularly when it affects glandular parts, is often followed by induration, which afterward continues for a greater or less time. Thus, when the testis has been inflamed, a hardness of the epididymis frequently remains during life. Such induration, however, is not at all malignant, and, consequently, very different from what is implied by a real scirrhus.

TREATMENT OF INFLAMMATION.

One principal difficulty in believing the fact of retardation of the circulation in the capillaries of an inflamed part, and a strong argument against the supposition of their being in a state of debility, is, that the most effectual treatment of common inflammation consists of means which are generally of a debilitating nature, as bleeding, purging, &c. And surgeons are still farther attached to the theory of increased velocity of the blood's motion in the part affected, by the recollection of the local augmentation of temperature, the throbbing, and the instantaneous return of the red colour, after the discontinuance of any pressure by which the redness has been momentarily removed at some point of the inflamed surface. These, too, are all so many facts, which, as far as I can judge, are admitted by the generality of reasoners, whatever may be their particular theory. At the same time, it appears equally well proved, by careful microscopical experiments, that, in the capillaries of the part which is directly the seat of inflammation, there is a retardation, and sometimes even a stagnation, of the circulation. But this is not all: it is farther manifested, that the capillaries are considerably dilated, the blood in them materially altered, and that these phenomena are followed by an increased action of the larger arteries leading to the part affected. Now, I think, if we remain contented with these obvious circumstances, and dismiss the hypothesis of debility of the capillaries, not only the necessity for venturesome conjectures may be avoided, but a more rational account delivered of the principles of the efficacy of the usual mode of treatment. Thus, I would not presume to offer any supposition why the capillaries are dilated, and why the motion of the fluid in them is retarded, but would be satisfied with a knowledge of the facts, so as to elude a source of endless controversy, viz. the question, whether these changes proceed from debility of the said vessels, or other causes? In the view which I take of the nature of phlegmonous inflammation, I consider the following circumstances proved: 1. The dilated state of the capillaries in the immediate seat of inflammation. 2. The retardation, or even stagnation, of the circulation in them. 3. The increased action or excitement of the larger arteries leading to the inflamed part. All these three main points seem to me to be fully established by the investigations and experiments both of Dr. Wilson Philip, and Dr. Hastings; and I may make the observation, though aware that the latter gentleman does not regard increased action of the larger arteries as a constituent and necessary part of inflammation, because cases occur in which no such excitement can be detected (*On Inflammation*, *p.* 104); for I here put out of consideration chronic inflammation, which I believe is entirely a different process, bearing no resemblance to the acute forms of the disorder, either in the state of the capillaries, or of the larger arteries. Assuming the above points as proved, it is to be inquired, whether other facts, such as the heat and throbbing in the inflamed part, the instantaneous return of redness to the spot which has been touched, and the efficacy of common treatment, are reconcileable with them or not. I am disposed to think they are; for it is only asserted that the passage of the blood is more or less obstructed in the capillaries in the seat of the inflammation; and the larger arteries leading to them are for the most part obviously in a state of increased action, whereby a greater quantity of blood must be supposed to be determined towards the part. Now, as this augmented quantity of blood cannot pass freely through the smaller vessels in the immediate place of inflammation, it must be thrown into such arteries in the neighbourhood as are capable of receiving it, so that, in fact, the theory of obstruction of the capillaries may not be altogether incompatible both with increased action and quickened circulation in the arteries directly around the parts in which there is a retarded circulation in the capillaries. This view of the subject, I think, is not liable to greater perplexity in the explanation of the heat, throbbing, &c. than former doctrines, involving the contradicted notion of there being an increased action and an augmented velocity of the blood's motion in *all* the arteries of the part affected.

Resolution being the most favourable termination of common inflammation, it is of course the object at which the surgeon generally aims in the treatment. Dr. Philip's very ingenious view of inflammation leads him to suppose that resolution arises from the debilitated capillaries being excited to due action by the increased action of the larger arteries.—(*On the Vital Functions*, *p.* 298.) But I am of opinion, that the doctrine of debility of the capillaries, and the hypothesis of their being strengthened by the excitement or increased action of the larger vessels, are by no means satisfactory, and perhaps not very intelligible. On the contrary, if the capillaries are already so weak as to be distended by the ordinary impulse of the blood, how are they to be restored to their natural dimensions and functions by any increased action of the larger arteries? the effect of which, I should conceive, would be to gorge them still more with blood, and produce even a greater dilatation of them. Were the above reasoning correct, it would follow, that a principal indication in the treatment would be to promote the increased action of the larger arteries, whereby so much supposed benefit is communicated to the debilitated capillaries. Yet such practice is contrary to the dictates of experience, and is even inconsistent with the principles on which Dr. Philip himself thinks the treatment should be founded. Indeed, the following directions are such as I imagine will be perfectly approved of by practitioners, who, far from looking upon the increased action of the arteries as a means of relief, are accustomed to do every thing in their power to lessen and resist it. "All the local means (says Dr. Philip) are calculated either to lessen the contents of the morbidly distended vessels, or to excite these vessels to expel them. The general means are regulated by the effects produced by the disease on the more distant vessels, through the medium of the nervous system; the objects of this part of the treatment being, neither to allow the action of these vessels to fall so low that it is incapable of supporting any degree of circulation in the debilitated vessels, nor to become so powerful as farther *to distend by gorging them with blood. Thus, when the symptoms of active inflammation run high, we lessen the vis à tergo:* when gangrene is threatened, we increase it."—(*W. Philip, on the Vital Functions*, *p.* 285, *ed.* 2.) In short, as

soon as the fact is established that a strong flow of blood towards an inflamed part tends to aggravate the disorder, all difficulty ceases in reconciling the usual means of relief to that theory of inflammation, which takes into the account a retarded state of the circulation in the distended capillaries.

Let us now devote a few pages to the consideration of the means to be employed for the relief of inflammation.

Removal of exciting causes.—In all cases, the first circumstance to be attended to is the removal of all such exciting causes as may happen to present themselves. If the irritation of a splinter were to excite phlegmonous inflammation, who would not of his own accord directly take away the extraneous body? In wounds, foreign substances frequently excite inflammation, and ought to be taken away as speedily as possible; splintered pieces of bone often give rise to the affection, and require removal; the head of a bone, being out of its place, may press and inflame the part on which it lies; and who does not immediately see the propriety of putting it back into its natural situation? These and other similar exciting causes may often be detected and removed at once, and this is doing a great deal towards the cure and even the prevention of inflammation. However, many of the exciting causes of this affection are only of momentary application; yet, though their action is thus short, the process of inflammation must follow, as a kind of salutary operation, without which, the injured organization and tone of the parts, still remaining, could not be rectified again. Hence, besides taking away the remote cause, whenever this can be done, it is proper to moderate, by other means, the increased action of the larger arteries, and lessen the velocity of the blood's motion towards the inflamed part.

Bleeding.—As there is reason to believe that in common inflammation a greater quantity of blood is impelled towards the inflamed part than in the natural state, and experience proves that nothing has a more powerful effect in checking the disorder, than diminishing the determination of blood to the part, bleeding must be a principal means of relieving inflammation: it lessens the action of the whole sanguiferous system, and, of course, of that part of it which is directly concerned in regulating the quantity of blood transmitted to the part affected. On the principle also of lessening the whole mass of blood in the circulation, it must have a similar effect.

Bleeding, however, is often misemployed, especially when regarded as the only remedy for inflammation, and other steps are neglected. The general obstinacy and vehemence of the process in weak constitutions, prove that bleeding is not invariably proper, and in such individuals it often appears as if their general irritability and the difficulty of curing the inflammation, were in a ratio to their weakness. It is a common notion, that when inflammation is complicated with disorder of the chylopoietic organs, blood should be taken away with great circumspection; but for its correctness I cannot vouch, any more than I can vouch for the truth of a common supposition, that cases of inflammation in London do not require bleeding to the same extent as similar cases in the country. The hypothesis is beginning to be doubted by the sagacious part of the profession, and has now less influence than formerly upon practitioners, who are getting into the wise custom of examining things with their own senses, and thinking for themselves.

A great deal of induration, with little pain and heat in the inflamed part; the probability of a long and copious suppuration, as is the case in many compound fractures; and the connexion of the inflammation with a want of tone in the part; are particular instances in which the practitioner should be sparing of this evacuation. Bleeding is sometimes quite unnecessary, when the local inflammation and symptomatic fever are trivial, when the patient is feeble or very old, and when the cause of the affection can be entirely removed.—(*Richter's Anfangsgr. b.* 1.) However, bleeding is as necessary in old as in young persons, if the general and local effects of genuine phlegmonous inflammation be severe. Also, as Langenbeck has explained, even in feeble individuals, the inflammation may depend upon occasional causes, which are so powerful in their operation as to be followed by great reaction. Sometimes, after having amputated the limbs of patients, already labouring under hectical symptoms, he assures us he has practised bleeding in consequence of such inflammatory reaction, with the best effect.—(*Nosologie, &c. b.* 1, *p.* 261, 262.)

On the other hand, bleeding is highly beneficial where the inflammation is uncomplicated with any previously existing disorder of the gastric system, while it is considerable in extent and degree, and attended with a good deal of febrile disturbance. The same practice is also strongly indicated, when the part affected is very sensible, and highly important, in regard to its office in the system. Thus the lancet must be freely employed in acute ophthalmy, or inflammation of the eye, which is a most sensible part, and in inflammation of the lungs, brain, or stomach; organs, the sound state of which is essential to the regular continuance of all the various operations in the animal machine; and if a successful effort be not promptly made to stop such inflammation by the most vigorous means, death itself will be the result.

In general, bleeding may be said to be indicated when the patient is young, robust, and plethoric; when the local and constitutional symptoms are severe; when the patient has been living well and eating a great deal of animal food, so as to have a decidedly inflammatory diathesis (see *Langenbeck's Nosologie, &c. b.* 1, *p.* 261); when the cause of the disorder can neither be removed nor diminished; and when there is a strong motive for wishing to avoid the formation of matter. Inflammation of the eye is a case illustrative of the truth of the last observation; for, if suppuration take place in this organ, the common consequence is so serious a destruction of its internal structure and organization, that the future restoration of sight is totally impossible. In the examples falling under the conditions specified as requiring blood to be taken away, it is sometimes necessary frequently to repeat the evacuation.

The efficacy of bleeding is greater the sooner it is practised, and the more suddenly the blood is evacuated. Bleeding near the part affected is usually more effectual than when done in a remote situation. Hence, in inflammation of the eye or brain, it is often considered most advantageous to take blood from the temporal artery, or by cupping on the temples.

"In many inflammations, particularly those of the parts contained in the three great cavities of the head, chest, and belly, general blood-letting (says a judicious writer), if not the only, is the principal remedy, to which we can trust for a cure. The quantity of blood, which, in these inflammations, it is necessary to take away, varies according to the violence of the inflammation, the temperament, strength, and habits of the patient, and according to the structure, functions, and situation of the organ in which it occurs. From twelve to twenty ounces, or even more, ought generally to be drawn every time we have occasion to use the lancet in the cure of inflammation, and bleeding to this extent may be repeated two or three times in the course of the first twenty-four hours, according to the effects which it seems to produce, as well as according to the violence and urgency of the symptoms. In inflammation of internal parts, we judge of the effect of bleeding, and of the necessity of a repetition, from the feeling and continuance of pain, from the state of the pulse, and also from the appearance of the blood which has been last drawn.

"A partial, and in some instances an almost complete, cessation of pain takes place even during the operation of blood-letting. This is always a favourable symptom, and indicates that the inflammation has made no great nor very alarming progress. In other instances, the relief from pain, though inconsiderable at the time of bleeding, becomes afterward more sensible and the other symptoms of inflammation abate in nearly the same proportion; while, in other instances again, the pain is either not relieved by the bleeding, or, if relieved, the relief is but of short duration. These last are cases in which, the other symptoms of inflammation continuing unabated, recourse must be had again to the use of the lancet, and as much blood drawn as can be done with safety to the patient.

"The changes which take place in the state of the pulse, either with regard to its frequency or strength, during or soon after the abstraction of blood, though they afford criteria by which we may judge of the

state of the inflammation, and of the effects of the bleeding, are by no means marks so sure of the advantage which has been obtained, as that derived from the cessation of pain.

"In some inflammations of the head, for example, the pulse is slower than natural, though it beats with its accustomed, or even with an increased, degree of strength. In inflammations also of the peritoneum and of the intestinal canal, we find the pulse not much quicker than natural, small, and contracted. We should deceive ourselves, therefore, were we to infer, that an increase of inflammation had taken place, because, in the first instance, the pulse had become quicker, and, in the second, fuller and stronger, during or soon after the abstraction of a quantity of blood.

"The pulse, it may be remarked, has often a contracted, cord-like feel in inflammation, and it may always be regarded as a favourable event, when it becomes softer, fuller, and slower, during or soon after blood-letting."—(See *Thomson's Lectures on Inflammation*, *p.* 166, 168.)

Although Professor Langenbeck, in common with other practitioners, deems the change of the pulse and the abatement of pain as important considerations for determining how much blood should be taken away, he advises the surgeon never to forget, that when certain organs are inflamed, bleeding is always followed by a rise of the pulse. This reason leads him also to regard the cessation or continuance of pain, as a better criterion.—(*Nosologie, &c. b.* 1, *p.* 265.)

With respect to the buffy coat of the blood, Dr. Thomson states, that it is not by the buffy coat alone, but by the buffy coat in conjunction with the quantity and firmness of the coagulum, that we must judge of the propriety of any farther detraction. When the buffy coat has a firm and tenacious consistence, and when the pain continues unabated, we may conclude, that the inflammation is not subdued. But when the coagulum is soft and easily broken, and when the colour of the buffy coat is changed from a yellowish to a greenish hue, Dr. Thomson thinks that little or no benefit can be derived from bleeding. But as already mentioned, every practitioner should remember, that in particular constitutions, and in pregnancy, the blood taken away flaturally exhibits a buffy appearance, independently of inflammation.

The preceding remarks chiefly relate to *general* bleeding; for, in phlegmonous inflammation, *topical* bleeding is scarcely ever improper. It is always a point highly worthy of the surgeon's consideration, whether bleeding *in* or *near* the part will answer better than taking the blood from the *general habit*; for certainly less may be removed in this way, so as to have equal effect upon the part inflamed, and probably upon every other disease that is relieved by bleeding, with less injury to the constitution. Although, in many cases, the general habit is relieved by bleeding, yet it is the part affected which most requires this evacuation. That local bleeding has very considerable effects on the inflamed part is proved by the sudden relief which is often produced by the application of leeches in cases of gout. The mere use of leeches, without other measures, will also sometimes remove a tumour in the breast, having all the appearance of a scirrhus, which cannot be considered as inflammatory, so that topical bleeding extends its power farther than the mere checking of inflammation. Some part of its effect has been imputed to sympathy.—(*Hunter.*) There are three modes of performing topical bleeding; by cupping, by leeches, and by dividing or scarifying the dilated vessels leading to the inflamed part.—(See *Bleeding.*) Upon the head and face, leeches are commonly employed; upon the chest, either leeches or cupping; upon the abdomen, leeches; and upon the joints, either cupping or leeches. When the eye is inflamed, leeches may either be applied to the adjoining temple, or the dilated vessels of the conjunctiva may be scarified; or both methods may be adopted. When the inflammation extends quite to the surface of the body, leeches are always most eligible, as their bites cause less irritation in inflamed parts than the punctures of the scarificator or the pressure of cupping-glasses.

Purging.—The exhibition of mild laxative medicines and saline purgatives is a principal means of diminishing inflammation Purging does not produce such lasting weakness as is the consequence of bleeding, and, therefore, it is scarcely ever omitted, even when the abstraction of blood is deemed improper. Saline purges must lessen the quantity of circulating blood, inasmuch as they increase the secretion from the intestinal arteries; and therefore, they probably operate beneficially in the cure of local inflammation, much upon the same principle as bleeding. Mr. Hunter was of opinion, that purging lowers action, without diminishing strength, by which we are probably to understand, without producing a very lasting or permanent loss of strength. With respect to mild laxative medicines, none are superior to manna, rhubarb, oleum ricini, and the like; and of the saline purgatives the best are, the sulphate of soda, tartrite of potass, phosphate of soda, and sulphate of magnesia. It may here be remarked, that besides the benefit which the local inflammation derives from the judicious administration of purgatives, the costiveness and heat which usually attend the symptomatic fever, are also removed by the same means.

"Purgatives (says Dr. Thomson) are more or less required in almost every species of inflammation; but they are more peculiarly necessary in those which are accompanied with a high degree of fever, or with derangement of the digestive or biliary organs. In cases of inflammation which have a tendency to spontaneous resolution, they are almost always the best, and often the only remedies that are required."—(*Lectures on Inflammation*, *p.* 171.)

Considering the general approbation of the employment of mild saline purgatives in cases of inflammation I confess that I was not a little surprised to find merely the following short unfavourable notice taken of them by a celebrated foreign professor, in his account of the treatment of inflammation:—"As for purgatives, they must be used with discretion. There are none of them antiphlogistic, as has been pretended. They always produce more or less irritation, and can only be applicable when the cause of the inflammation is in the intestinal canal. In the beginning of the complaint we ought, therefore, in general to abstain from them, and confine ourselves to emollient glysters."—(*Boyer, Traité des Maladies Chirurgicales*, *t.* 1, *p.* 39.)

Diaphoretic and nauseating medicines.—Medicines which have the power of producing sickness lessen for a time the action, and even the general powers of life. This is in consequence of every part of the body sympathizing with the stomach; and the effect may be very quickly excited. Sickness lowers the pulse, makes the small vessels contract, and rather disposes the skin to perspiration. But nothing more than nausea should be caused; for vomiting rather rouses than depresses.—(*Hunter.*) Nauseating medicines, employed after bleeding has been practised once or twice, are often productive of considerable benefit; but there are some affections in which they cannot be used, such as inflammation of the stomach and intestines. In all superficial inflammations, however, they may be safely and advantageously exhibited, as well as in most inflammatory affections internally situated. In inflammation of the dura mater and brain, and, indeed, in every instance in which there is an urgent reason for putting as sudden a check as possible to the continuance of the affection, the employment of nauseating doses of antimony is most strongly indicated. The tartrite of antimony (emetic tartar) is the medicine on which practitioners place the greatest reliance, and it is to be prescribed for the purpose of exciting nausea as follows:—℞. Antimonii tartarisati grana duo; aquæ distillatæ uncias quatuor. Misce et cola. Dosis, uncia dimidia sextâ quâque horâ.

The safest diaphoretics are citrate of potass, acetate of ammonia, and tartrite of antimony, and James's powder. The two latter, from their effects in producing nausea and weakening the pulse, are sometimes most efficacious, as already stated.

"The warm bath seems to act (as a modern writer says), not only by increasing the tendency to perspiration, but also by occasioning a determination of blood to those parts of the body to which it is more immediately applied. It is in this way that bathing the feet seems to relieve inflammatory affections of the head and throat. I have not seen any experiments, nor am I acquainted with any, which have been made with a view to ascertain its use in the inflammations of the

chest; but in all inflammations of the belly, and of the viscera contained within that cavity, there are no other means of cure, blood-letting excepted, which afford such sudden and permanent relief, as that which is obtained from hot fomentations and warm bathing."—(See *Thomson on Inflammation*, p. 173.)

Opium.—The majority of surgeons entertain an insuperable objection to the administration of opiates in almost all cases of inflammation, and the aversion to this practice is for the most part deducible from the recollection of opium being a powerful stimulant. The plan, however, has its advocates.—(*B. Bell, Richter, &c.*) One of its strongest partisans tells us, that opium particularly lessens the disturbance of inflammation, and allays pain, which is at once a principal symptom of the process, and a cause of its augmentation, as well as that of the fever. Opium also quiets the inordinate action of the solids, the mental agitation and restlessness, so powerfully, that it well deserves the name of the grand *antiphlogistic remedy*. It likewise occasions a moisture on the surface of the body, which experience shows is eminently serviceable in all inflammations affecting the skin. When given with this view, it is usually conjoined with antimony, camphor, calomel, or ipecacuanha. The administration of opium is a general practice in all painful inflammations arising from external causes, and *it is attended with perfect safety when evacuations from the bowels and bleeding have been previously put in practice.* Care must be taken to give it in sufficient doses; for small quantities not only fail in fulfilling the object, but frequently produce quite an opposite effect. During its employment, the bowels should be kept open with glysters. The efficacy of opium chiefly manifests itself in the early stage of the affection; for as soon as the inflammatory fever has extended itself to the whole system, it loses its beneficial virtues. Hence, in cases of external injuries, it is to be given the first two days, immediately after bleeding. It is to be given as soon after the accident as possible, in order to tranquillize the mental alarm, and if convenient, towards the evening, for the sake of procuring a quiet night.—(*Richter.*) Evacuations being premised, says the other advocate for this medicine, the next object of importance is to procure ease and quietness to the patient, which, in cases of inflammation, are often of more real service, than any other circumstance whatever. The most effectual remedy for this purpose is opium, which, when the pain and irritation are considerable, as very frequently happens in extensive inflammations, should never be omitted. In large wounds, especially after amputations and other capital operations, and in punctures of all kinds, large doses of opium are always attended with remarkably good effects. In all such cases, however, opium, in order to have a proper influence, should be administered in very large doses; otherwise, instead of proving serviceable, it seems rather to have the contrary effect.—(*B. Bell.*) According to modern observations, morphine is the principle in opium, that tranquillizes without producing the ill effects of common opium, and of course its preparations are peculiarly suited for cases of inflammation.

On the contrary, those who are averse to the use of opium remark, that in acute inflammation daily experience shows, independently of every theory, that the exhibition of this medicine increases the general fever, and aggravates the local action. Even given as a preventive of inflammation, after operations, anodynes are almost uniformly hurtful, producing restlessness, heat, thirst, and afterward headache, sickness, and frequently troublesome vomiting.—(*Burns.*)

According to Dr. Thomson, "those diaphoretics, into the composition of which opium enters, seem to be better adapted for inflammation attended with fever of a typhoid character, or for cases where the inflammation has existed for a considerable time before diaphoretics are employed. Given at an early period in acute inflammatory diseases, opium never fails to excite vascular action, and to aggravate all the symptoms of fever. Opium, therefore, is not to be used, unless to allay the pain and irritation from a surgical operation, or from the recent infliction of an external injury. Indeed, unless when the patient is very nervous, and complains much of pain, its use, even after chirurgical operations, had, I believe, in general, better be abstained from, as it almost never fails to add to the violence of the symptomatic fever which is the necessary consequence of the operation. Its effects are often very beneficial, when the period of this fever has passed over."—(See *Lectures on Inflammation*, p. 172.) Upon the whole, candour obliges me to own, that the majority of surgeons in this country are decidedly against the general use of opium in inflammation; but after the performance of severe operations, and in all instances attended with excessive pain, truth, I believe, will justify my saying, that they are in favour of the exhibition of this remedy; and, no doubt, the preparations of morphine, or those from which the stimulating principles of the drug have been removed, while the anodyne are retained, ought here to be preferred.

Diet and Regimen.—In all cases, the surgeon is to forbid the use of wine and spirits; and, when the inflammation is at all considerable, the same prohibition is to be made in regard to animal food. Watery, cooling, mucilaginous drinks are proper; for they keep off thirst and heat, promote perspiration, and tend to sooth the increased action of the whole arterial system. For this purpose, whey, buttermilk, barley-water, decoctions of dried fruits, water-gruel, &c. may be given.

When diluent drinks "are intended to allay thirst, as well as to promote perspiration, the addition of some vegetable acid, such as lemon-juice, or cream of tartar, renders them in general very palatable to patients. In the earlier stages of inflammation, and where the object is to induce a moisture on the skin, the mineral acids, though they might serve to quench thirst, are not to be employed, as they tend rather to check than promote the flow of sweat."—(*Thomson on Inflammation*, p. 172.)

The chamber in which the patient lies should not be warmer than his comfort requires; for heat tends powerfully to keep up an increased action of the sanguiferous system. For the same reason, the patient should not be covered with a superfluous quantity of bed-clothes.

The whole body, but more especially the inflamed part, should be preserved in as complete a state of rest as possible. Every one knows, that all motion, exercise, and muscular exertion accelerate the circulation, and hence must have a pernicious effect on inflammation, by determining a larger quantity of blood to the part affected.

Applications.—With the exception of what has been stated concerning topical bleeding, all the foregoing remarks relate to the *general* treatment of inflammation: the *local* means remain for consideration.

It has been already observed, that phlegmon is attended with an increase of heat in the part affected, and it is an acknowledged and well known fact, that the action of the arteries, as well as every other operation in the animal economy, is promoted and increased by the influence of heat. For this reason, an obvious indication arises, viz. to reduce the temperature of the inflamed part, by the topical application of cold, and, in particular, by continually abstracting the heat evolved in the part, by keeping up a constant evaporation from its surface.

"Of the local remedies applied directly to inflamed parts (says Dr. Thomson), cold is undoubtedly one of the most powerful. In reducing the temperature, cold diminishes the morbid sensibility and pain of inflamed parts; and, probably, in consequence of this, the action also of the vessels by which the inflamed parts are supplied with blood. The most common mode of employing cold is by the application to the part inflamed of cloths which have been dipped in cold water. These are to be repeated as often as they become warm, or any relief is experienced by the patient from their use. When the inflammation is seated in the remote parts of either the upper or lower extremities of the body, the inflamed part itself may be immersed in water. This immersion, as I shall afterward have occasion to mention, has often been found useful in superficial burns. In order to increase the effect produced by cold, it has been proposed to reduce the temperature of the water below that of the surrounding atmosphere, by a proper mixture of saline bodies, as some of these are known to produce cold during their solution in water, or even in very urgent cases to apply ice or snow. The ice, however, must not be applied too long, nor in too large a quantity; for it very quickly reduces the temperature of the part to which

it is applied, and, in some instances, has been known to occasion gangrene, &c."—(*On Inflammation*, *p.* 180.)

With the cold water applied to phlegmonous inflammation, it is usual to blend some remedies, which are astringent, and supposed to have also a sedative quality. The acetate of lead, sulphate of zinc, and vinegar seem now, indeed, to have acquired permanent celebrity for their efficacy in resolving inflammation.

Extensive experience and long established trials, have now fully confirmed the virtue of all those local remedies, in which the acetate of lead is the active ingredient. M. Goulard, and other French surgeons, found, that the objections to the employment of many other sedative applications in the treatment of inflammation did not exist against the use of this preparation of lead. The universal assent of modern practitioners proves, indeed, that the acetate of lead, as a local application for genuine phlegmonous inflammation, is certainly unsurpassed, if not unrivalled, in point of efficacy.

The preparations of lead are recommended by M. Goulard, as applicable to almost every stage of inflammation. When swellings have fully suppurated, the employment of what he calls the *extractum saturni*, will generally render it unnecessary to open them. Even in gangrene, the solution of lead is represented, by this partial writer, as a remedy deserving of the greatest confidence.

But, notwithstanding the above exaggeration, every man of experience and observation will allow, that, while there is a chance of accomplishing resolution, no local applications to phlegmonous inflammation are in general so proper as cold lotions, containing the acetate of lead.

"The manner in which it operates in curing inflammation (as Dr. Thomson observes) is not known to us, nor is it at all times easy to distinguish between the share which the lead has in allaying inflammation, and that which is to be attributed to the coldness of the water in which it is dissolved. No one, however, will doubt the efficacy of this remedy, who has ever felt it in his own body, or witnessed in others the soothing and agreeable effects which it produces in excoriations of the skin, or in inflammation of mucous membranes. Lead is a remedy which is often highly useful in excoriations from friction, in punctured wounds with inflammation of absorbent vessels, veins, nerves, &c., in slight burns, in cutaneous heat, eruptions of the face, in fractures and dislocations, in the inflammation attending scirrhus and cancer, syphilis and gonorrhœa, in wounds accompanied with excoriation from the discharges they emit, and in wounds attended with a burning sensation of pain."—(*P.* 182.)

From the poisonous qualities of lead, when taken into the system, and from the possibility of this mineral being absorbed from the surface of the body, objections have arisen against the free use of its preparations, even as outward remedies, in cases of inflammation. Certain it is, however, that though the possibility of such absorption is proved by the occurrence of the disorder called the *colica pictonum*, which originates in painters from the white lead absorbed into the system, yet any ill effects from the use of lead, as an application to inflamed parts, are so rare, that they can hardly form a serious objection to the practice. It is a fact, that in inflamed parts there is an impediment to absorption, and this circumstance must tend to render the employment of lead a matter of safety. Mr. B. Bell observes, that in all the experience which he had had of the external application of lead and its preparations, and in many cases, particularly of burns, where he had known the greatest part of the surface of the body covered with applications of this description for days, nay for weeks together, he did not recollect a single instance of any disagreeable symptom being ever produced by them. Nor has Dr. Thomson ever seen the colica pictonum follow the use of Goulard.—(See *Lectures on Inflammation*, *p.* 183.)

A lotion composed of acetate of lead, vinegar, and water, is very commonly employed. ℞. Plumbi Acetatis ℥ss. Solve in Acet. pur. ℥iv. Et adde Aq. Fontanæ distill. ℔ij. The vinegar makes the solution more complete. In all common cases, a tea-spoonful of the liquor plumbi acetatis, blended with a pint of water, to which an ounce of spirit of wine has been added, will be found an eligible lotion. Occasionally, bread-crumb is moistened in the fluid, and applied in the form of a poultice; but linen dipped in the lotion and kept constantly wet with it, is mostly preferred Thus a continual evaporation is maintained, and of course a regular abstraction of heat.

When the surgeon is afraid of employing a solution of lead, he may try one of the sulphate of zinc. One drachm of this substance is to be dissolved in a pint of water, and linen, well wet with the lotion, is to be applied to the inflamed part.

Many practitioners impute little real efficacy either to the acetate of lead or sulphate of zinc contained in the above applications; and they attribute all the good that is produced entirely to the evaporation kept up from the surface of the inflamed part, and to the coldness of the fluid in which the metallic salts are dissolved. Surgeons who entertain these sentiments often apply simple cold water, or spirit of wine largely diluted.

There are particular cases of inflammation, in which the extravasation of blood and lymph, in the interstices of the inflamed part, is exceedingly copious, and the swelling considerable, but the pain and redness not particularly great. In such instances, it is an indication to rouse the action of the absorbents, in order that those vessels may remove the extravasated fluid, and with this view, a more powerful discutient lotion may be employed than in other cases, and sometimes it is even better to use embrocations and liniments, than any sort of lotion. The following discutient lotions are often employed:—℞. Ammoniæ Muriatæ ℥ss. Aceti; Spiritûs Vini rectificati; sing. ℔j. M. ℞. Liq. Ammon. Acet. Spir. Vini rectif.; Aq. Distillatæ; sing. ℥iv. M. The Liq. Ammoniæ Acet. answers very well by itself.

When the part affected with inflammation is not very tender, or when it lies deep, applications of the vegetable acid are often had recourse to with considerable advantage; and the most effectual form of using it seems to be a poultice made with vinegar and crumb of bread. In such cases, it has been thought, that an alternate use of this remedy, and the saturnine lotion, has produced more beneficial effects than are commonly observed from a continued use of one of them.—(*B. Bell.*) However, surgeons of the present day seem to think, that vinegar can be as advantageously applied in the form of a lotion, as in that of a poultice, and certainly with less trouble.

Alcohol and ether have acquired some celebrity as local remedies for inflammation. No doubt one great reason why they are not more extensively used for this purpose is, the expense attending such treatment, as these fluids evaporate with great rapidity. Alcohol may possibly prove useful from its astringent qualities; but it seems much more rational to impute both its virtue, and that of ether, to the manner in which their evaporation lowers the temperature of the inflamed part.

Warm Applications.—The absurdity of attempting to reconcile every useful practice with a philosophical theory, is in no instance more strikingly exemplified, than in the opposite sorts of local applications, which are of service in inflammation. The generality of cases undoubtedly receive most relief from the use of cold sedative astringent lotions; but there are constitutions and parts which derive most service from the local employment of warm emollient remedies.

Were I to endeavour to define the particular instances in which the latter applications avail most, I should take upon me a task which has baffled all the most able surgical writers. The first stage of acute ophthalmy, and the hernia humoralis, or inflamed testicle, may be specified, however, as examples, in which, generally speaking, warm emollient applications are better than cold astringent ones. Yet, even with respect to inflammation of the testis, there is some difference of opinion about the superiority of cold or warm applications. Mr. James's sentiments are as follows: in the treatment it is of importance to consider the differences of the cause; thus, in mumps and rheumatism, the constitution is chiefly to be attended to, and cold applications are certainly improper. When it (the inflammation of the testis) arises from a blow, after leeches have been freely employed, fomentations are the best remedy. But Mr. James thinks that this is not the case, in many instances of inflamed testicle from gonorrhœa, where cold applications are preferable; but he owns that the feelings of the patient will

best determine the point.—(*James on Inflammation*, p. 164.)

"Fomentations or embrocations with warm water, (as a judicious writer has remarked) are often a very powerful means of abating internal inflammation. This effect is very apparent in some of the deeper-seated inflammations, as in the inflammation of the urinary bladder, intestines, or other viscera contained within the cavity of the abdomen. The warmth, in this case, may be applied to the surface of the abdomen, by bath or fomentation, or in the way of injection by the anus, &c. In some inflammations of the joints, warmth also is found to be very useful. These, however, are inflammations which have a tendency to the chronic state."—(See *Thomson on Inflammation*, p. 188.)

If we may judge by the feelings of certain patients, there are undoubtedly particular constitutions in which the local use of warm remedies produces greater relief than that of cold ones. This circumstance, however, does not generally happen; and, as warm emollient applications of all kinds have the most powerful influence in promoting suppuration, a fact admitted by every experienced practitioner, the use of such remedies, while the resolution of inflammation is practicable, must be highly censurable. But I am ready to grant, that in all cases of inflammation which manifestly cannot be cured without suppuration, the emollient plan of treatment ought to be at once adopted; for the sooner the matter is formed the sooner the inflammation itself is stopped. The inflammation attending contused and gun-shot wounds, and that accompanying boils and carbuncles, are of this description. The inflammation originating in fevers commonly ends in suppuration; and in such instances, perhaps, it might be advantageous also to employ at once the emollient treatment.

Warmth and moisture together, in other words fomentations, are commonly had recourse to; but it is observed by Mr. Hunter, that when the warmth is as much as the sensitive principle can bear, it excites action. Whether it is the action of inflammation, or the action of the contraction of the vessels, is unknown. We see that many patients cannot bear warmth, and therefore it might be supposed to increase the action of dilatation and do harm. But if the pain should arise from the contraction of the inflamed vessels, benefit would be the result; though we must doubt that this change is produced, as making the vessels contract would probably give ease.

From the preceding observations we must perceive how vain it is to theorize on this subject, which even puzzled the genius and penetration of a Hunter. In addition to what has been already observed, I feel totally incapable of giving any useful practical advice, with respect to those cases in which warm emollient applications should be used in preference to cold astringent ones. I can, however, with confidence remark, that the surgeon who consults the feelings and comfort of the patient on this point will seldom commit any serious error. Hence, in all cases in which the first kind of topical applications seem not to produce the wonted degree of relief, let the second sort be tried. From the opportunity of comparison a right judgment may then be easily formed.

The poultice, made of the powder of linseed, is so easily prepared, that the old bread and milk poultice is now seldom employed. As much hot water is to be put into a basin as the size of the poultice requires, and then the linseed powder is to be gradually mixed with the water till the mass is of a proper consistence. Frequently a little sweet oil is also added, to keep the application longer soft and moist.

Fomentations are only to be considered as temporary applications, while the emollient poultices are the permanent ones. The former are, at most, never used more than three times a day for the space of about half an hour each time. Two of the best are the following:—℞. Lini contusi ℥j. Chamæmeli ℥ij. Aq. distill. ℔vi. Paulisper coque et cola. Or, ℞. Papaveris albi exsiccati ℥iv. Aq. puræ ℔vi. Coque usque remaneat ℔j. et cola.

Some practitioners, however, are inclined to think warm water alone quite as efficacious as the decoctions of particular herbs. Thus Dr. Thomson observes, "herbs are now seldom used in the way of fomentation, unless in compliance with ancient custom, or with the prejudices of particular individuals. The discutient power of the warm water may be increased by the addition of various substances, such as vinegar, spirits of wine, saline substances, such as common salt, acetate and muriate of ammonia. But these warm and stimulating embrocations are used chiefly in the passive, chronic, or more indolent species of inflammation."—(See *Lectures on Inflammation*, p. 189.

By pursuing the above treatment, the resolution of the inflammation will in general begin to take place, either in the course of three or four days, or in a shorter space of time. At all events, it may usually be known before the expiration of this period how the disorder will terminate. If the heat, pain, and other attending symptoms abate, and especially if the tumour begin to decrease, without the occurrence of any gangrenous appearances, we may then be almost certain, that, by a continuance of the same plan, a total resolution will in time be effected.

On the other hand, when all the different symptoms increase, and particularly when the tumour becomes larger and softish, attended with a more violent throbbing pain, we may conclude that the case will proceed to suppuration. Hence an immediate change of treatment is indicated, and such applications as were proper while resolution seemed practicable, are to be left off and others substituted. This remark relates to the employment of cold astringent remedies, which, when suppuration is inevitable, only do harm by retarding what cannot be avoided, and affording no relief of the pain and other symptoms. If the inflammation, however, should already be treated with emollients, no alteration of the topical applications is requisite, in consequence of the inevitability of the formation of matter. Indeed, emollient poultices and fomentations are the chief local means both of promoting suppuration, and diminishing the pain, violent throbbing, &c. which always precede this termination of phlegmonous inflammation.

But besides the substitution of warm emollient applications for cold astringent lotions, practitioners have decided, that it is also prudent, as soon as the certainty is manifest, to relinquish the free employment of evacuations, particularly blood-letting, and to allow the patient a more generous diet. When the system is too much reduced by the injudicious continuance of rigorous antiphlogistic treatment, the progress of the ensuing suppuration is always retarded in a disadvantageous manner, and the patient is rendered too weak to support either a long-continued or a profuse discharge, which it may not be possible to avoid.

I shall conclude this article with briefly noticing blisters, rubefacients, issues, and synapisms, as means often employed for the relief of particular cases of inflammation. "Blisters (says Dr. Thomson) are never applied to a part which is actually inflamed. They seem to be chiefly useful by exciting inflammation in a contiguous part. It is from this tendency which blisters have to produce inflammation, and of course a certain degree of fever, that they are seldom to be employed in acute inflammatory cases till the constitutional symptoms are by other means in some measure subdued."—(*P.* 187.)

"Of the same nature, though milder in their operation than blisters, are the whole class of rubefacients. They produce a determination of blood to the parts to which they are applied, and, in a manner not yet well understood, occasion a diminution in the action of the vessels, and consequently in the quantity of blood with which the inflamed parts are supplied. This influence is exerted more or less directly in different instances. The extremities of the intercostal arteries may open both on the pleura lining the chest, and on the surface of the skin covering it, and whatever excites an increased flow of blood into one of these textures, may be conceived to be attended with a proportionally diminished flow into the other texture. But blisters are found by experience to be efficacious in removing inflammation where no communication whatever can be traced between the blood-vessels of the inflamed part and that to which the blister is applied. We have examples of this mode of action in the beneficial effects obtained from the application of blisters in inflammation of the brain and the membranes immediately covering it, of the lungs and intestines, or of any of the viscera contained in the cavity of the abdomen. The nearer in such instances the blister or rubefacient can

be applied to the part inflamed, the greater is the relief obtained: and in general, I believe, it may be laid down as a rule, that the relief which they afford will be proportional to the degree of inflammation which they excite."—(See *Thomson on Inflammation, p.* 187. 189.)

Synapisms, blisters, and issues are in many instances applied in situations which are so remote from and unconnected by vessels with the inflamed parts, that it is impossible to explain their mode of operation, except through the medium of the nervous system. "The irritation of a synapism applied to the foot (says Dr. Thomson) may relieve an attack of gout in the head or stomach. Bathing the feet and legs gives relief in inflammation of the bowels; and the application of a blister or caustic to the neck may cure an inflammation of the eyes, &c."—(*P.* 189.) Here counter-irritation is the principle by which an explanation is usually attempted.—(See *Blisters.*)

INJECTION. A fluid intended to be thrown against, or into a part of the body, by means of a syringe. Thus port wine and water form an injection, which is used by surgeons for radically curing the hydrocele, and for this purpose it is introduced into the cavity of the tunica vaginalis, where it excites the degree of inflammation necessary to produce a universal adhesion between this membrane and the surface of the testicle.

Thus many fluid remedies are introduced into the urethra and vagina for the cure of gonorrhœa. In the article *Gonorrhœa* will be found an account of the best injections employed for its relief. A few additional remedies of this class are here subjoined.

INJECTIO ACIDI MURIATICI. ℞. Aquæ distil. ℥iv. Acid. Mur. gutt. vij. Misce. Has been used for the relief of the ardor urinæ in cases of gonorrhœa.

INJECTIO ALUMINIS. ℞. Alum. ℥j. Aq. pur. ℥vij. Misce. Successfully employed by Dr. Cheston, in affections of the rectum, either when the internal coat is simply relaxed and disposed to prolapsus, or when it is studded with loose fungated tumours.

INJECTIO CUPRI AMMONIATI. ℞. Liquoris Cupri ammon. gutt. xx. Aquæ rosæ ℥iv. Misce.

INJECTIO QUERCUS. ℞. Decocti quercûs ℔j. Aluminis purificat. ℥ss. Misce. Used when the rectum or vagina is disposed to prolapsus from relaxation, or in cases of gleet.

INOSCULATION denotes the union of vessels by conjunction of their extremities. It is generally synonymous with *anastomosis*, though sometimes a distinction is made; *anastomosis* signifying the union of vessels by minute ramifications, and *inosculation* a direct communication by trunks. The great use of inosculations is to facilitate and ensure the continuance of the circulation, when the large trunks of vessels are obstructed by pressure, disease, &c. Thus, in cases of aneurism, when the main artery of a limb is tied, the inosculations of the branches given off above the ligature, with other branches arising below it, form at once a channel, through which the lower part of the limb is supplied with blood. Were there no such arrangement in the human body as inosculations, aneurisms could never be cured by a surgical operation. So infinitely numerous, indeed, are these inosculations, that they do the office of the subclavian, carotid, and external and internal iliac arteries, when these vessels are tied, and upon this fact is founded the success of some of the most brilliant operations in modern surgery.—(See *Aneurism.*) Even the aorta itself may be perfectly obstructed, the circulation go on, and every part be fully supplied with blood.—(See *Aorta.*) In dogs, the abdominal aorta has been tied, without the circulation in the hinder extremities being stopped (see *the Experiments of Sir A. Cooper in Med. Chir. Trans. vol.* 2, *p.* 258); and the operation performed a few years ago, in Guy's Hospital, tends to prove that the same thing is possible in the human subject.—(See *Aorta.*) From the observations of the same distinguished surgeon, it appears, that the arteries which form the new circulation in a limb, after the obliteration of the principal artery, are not only enlarged but tortuous. Any great increase, however, in the diameter of the anastomosing vessels is but slowly produced; for Sir A. Cooper has injected a limb several weeks after the operation for popliteal aneurism, without being able to force the injection through communicating vessels into the parts below. The limb must have active exercise before the vessels enlarge much. On account of the arteries not very readily enlarging, the limbs of persons who have undergone the operation for aneurism are for a considerable time weaker than natural. They feel the influence of cold more, and are more disposed to ulcerate from slight causes. Hence, the utility of covering them with flannel or fleecy hosiery. Hence the rashness of applying cold washes, bandages, &c.—(See *vol. cit. p.* 249, *et seq.*)

In another place, the same gentleman has published an interesting description of the anastomoses of the arteries of the groin. "Hypothesis (says he) would lead to a belief, that anastomosing vessels would be numerous in proportion to the time which had elapsed from the operation; but the reverse of this is the fact; for, at first, many vessels convey the blood, originally conducted by the principal artery. But, gradually, the number of these channels becomes diminished, and, after a length of time, a few vessels, conveniently situated for the new circulation, become so much enlarged, as to be capable of conveying an equal portion of blood to that which passed through the original trunk."

The experience of Sir A. Cooper also tends to confirm the important fact, that "it is desirable in femoral aneurism, if not, indeed, in all others, to perform the operation in an early state of the disease," as the patient then recovers the use of the limb much more quickly than when the tumour has been suffered to attain a large size.—(See *Med. Chir. Trans. vol.* 4, *p.* 425, *et. seq.*)

INTESTINES WOUNDED. See *Wounds of the Abdomen.*

INTROSUSCEPTION, or *Intussusception.* Called also *Volvulus.* A disease, produced by the passing of one portion of an intestine into another, commonly the upper into the lower part.—(*J. Hunter.*) On this subject, Mr. Langstaff has published an interesting paper, in the *Edin. Surg. Journal, No. XI.*; which I shall take the liberty of freely quoting. He remarks, that the small intestines of children are so often affected with introsusception, in a slight degree, that most practitioners must have had opportunities of observing the form of the complaint. The greatest part of three hundred children, who died either of worms, or during dentition, at the Hôpital de la Saltpetriere, and came

under the examination of M. Louis, had two, three, four, and even more volvuli, without any inflammation of the parts, or any circumstances leading to a suspicion that these affections had been injurious during life. "These cases (says M. Louis) seem to prove that introsusception may be formed and destroyed again by the mere action of the intestines."—(*Mém. de l'Acad. de Chirurg. 4to. t. 4, p. 222.*) This opinion is confirmed by the authority of Dr. Baillie (*Morbid Anatomy, 2d edit. p. 162*), who observes that "in opening bodies, particularly of infants, an intussusception is not unfrequently found, which had been attended with no mischief; the parts appear perfectly free from inflammation, and they would probably have been easily disentangled from each other by their natural peristaltic motion." A rare example is on record, where the displacement existed at birth.—(*Beirel, De Intestinis se intus suscipientibus, &c. Helmst.* 1769.)

The disease, as Mr. Langstaff remarks, assumes a more dangerous, and indeed, generally, a fatal form, when it occurs at the termination of the small intestines in the cœcum. A contracted state of the part to be introsuscepted, and a dilatation of that portion of the canal into which this part must pass, are essential conditions to the formation of a volvulus; and they exist nowhere so completely as in this situation. The extent to which the affection here proceeds would appear almost incredible, if it were not proved by well authenticated facts. A person who considered the natural situation and connexion of the parts, would of course require the strongest evidence before he would believe that the ileum, cœcum, ascending and transverse portions of the colon, may descend into the sigmoid flexure of the latter intestine; nay, more, that they may pass through the rectum, and be protruded in the form of a procidentia ani. Such cases, however, are recorded.—(See *Lettsom's Case in Phil. Trans. vol. 76, and Langstaff, in Edin. Med. and Surg. Journal, No. XI.*)

This gentleman next relates the case of a child three months old, the body of which he inspected after death, and found to confirm the truth of the preceding account. The example was particular in there being, in addition to an extensive introsusception in the usual way, a smaller invagination in the opposite direction, like what probably occurred in the case related by Mr. Spry.—(*Med. and Physical Journal, No. XI.*) Sir E. Home mentions a retrograde introsusception, in which a worm was found coiled up round the introsuscepted part. The disease took place in a boy who had swallowed arsenic.—(See *Trans. for the Improvement of Med. and Chir. Knowledge, vol. 1.*)

If the following mode of accounting for introsusception be just, it will most frequently happen downwards, although there is no reason why it may not take place in a contrary direction; in which case, the chance of a cure will be increased by the natural actions of the intestinal canal tending to replace the intestine; and probably from this circumstance it may oftener occur than commonly appears.

When the introsusception is downwards, it may be called *progressive*, and when it happens upwards, *retrograde*. The manner in which it may take place is, by one portion of a loose intestine being contracted, and the part immediately below relaxed and dilated; under which circumstances, it might very readily happen by the contracted portion slipping a little way into that which is dilated, not from any action in either portion of intestine, but from some additional weight in the gut above. How far the peristaltic motion, by pushing the contents on to the contracted parts, might force these into the relaxed, Mr. Hunter could not determine, but he was inclined to suppose that it did not have this effect.

By this mode of accounting for an accidental introsusception, it may take place either upwards or downwards; but if a continuance or an increase of it arises from the action of the intestines, it must be when it is downwards, as we actually find to be the case; yet this does not explain those in which a considerable portion of intestine appears to have been carried into the gut below: to understand these, we must consider the different parts which form the introsusception. It is made up of three folds of intestine; the inner, which passes down, and, being reflected upwards, forms the second or inverted position, which, being reflected down again, makes the third or containing part, that is, the outermost, which is always in the natural position.—(*J. Hunter.*)

The outward fold is the only one which is active, the inverted portion being perfectly passive, and squeezed down by the other, which inverts more of itself, so that the angle of inversion in this case is always at the angle of reflection of the outer into the middle portion or inverted one, while the innermost is drawn in. From this we can readily see how an introsusception, once begun, may have any length of gut drawn into it.

The external portion, acting upon the other folds in the same way as upon any extraneous matter, will by its peristaltic motion urge them farther; and, if any extraneous substance is detained in the cavity of the inner portion, that part will become a fixed point for the outer or containing intestine to act upon. Thus it will be squeezed on, till at last the mesentery preventing more of the innermost part from being drawn in, will act as a kind of stay, yet without entirely hindering the inverted outer fold from going still farther. For it being the middle fold that is acted upon by the outer, and this action continuing after the inner portion becomes fixed, the gut is thrown into folds upon itself; so that a foot in length of intestine shall form an introsusception not more than three inches long.

The outer portion of intestine is alone active in augmenting the disease when once begun; but if the inner one were capable of equal action in its natural direction, the effect would be the same, that of endeavouring to invert itself, as in a prolapsus ani; the outer and inner portions, by their action, would tend to draw in more of the gut, while the intermediate part only would, by its action, have a contrary tendency.

The action of the abdominal muscles cannot assist in either forming or continuing this disease, as it must compress equally both above and below, although it is capable of producing the prolapsus ani.

When an introsusception begins at the valve of the colon, and inverts that intestine, we find the ileum is not at all affected; which proves that the mesentery, by acting as a stay, prevents its inversion.—(*J. Hunter.*)

From the natural attachment of the mesentery to the intestines, one would, at the first view of the subject, conceive it impossible for any one portion of gut to get far within another; as the greater extent of mesentery that is carried in along with it, would render its farther entrance more and more difficult, and we should expect this difficulty to be greater in the large intestines than in the small, as being more closely confined to their situation; yet one of the largest introsusceptions of any known was in the colon, as related by Mr. Whately.—(*Vide Phil. Trans. vol. 76, p. 305.*)

The introsusception appeared to have begun at the insertion of the ileum into the colon, and to have carried in the cœcum with its appendix. The ileum passed on into the colon, till the whole of the ascending colon, the transverse arch, and descending colon were carried into the sigmoid flexure and rectum. The valve of the colon being the leading part, it at last got as low as the anus; and when the person went to stool he only emptied the ileum; for one-half of the large intestines being filled up by the other, the ileum alone, which passed through the centre, discharged its contents.—(*J. Hunter.*)

Two questions of considerable importance present themselves to the mind in considering this subject; whether there are any symptoms, by which the existence of the affection can be ascertained during life? and whether we possess any means of relieving it, supposing that its existence could be discovered? The symptoms attending an introsusception, are common to inflammation of the intestines, hernia, and obstruction of the canal, from whatever cause, and a volvulus is the least frequent cause of such symptoms. In the case published by the above gentleman, and in those related by Mr. Hunter and Mr. Spry, the seat of the disease was clearly denoted by a hard tumour on the left side of the abdomen. This circumstance, together with the impossibility of throwing up more than a very small quantity of fluid in glysters (*Hevin, Spry, Langstaff*), and the presence of the other symptoms, would lead us to suspect the nature of the disorder. If the invaginated portion descended so low as to protrude through the anus, and we could ascertain that it was not an inversion of the gut, the case might

be considered as clear, and we should have no hesitation in delivering a prognosis, which, by preparing the friends for the fatal termination, would exonerate us from all blame on its occurrence.—(*Langstaff.*)

Mr. Bullin, of Fleet-market, lately attended a man who died of an introsusception of the ileum and cœcum into the colon, in which latter bowel there was a very close stricture by which the farther descent of the other intestines had been impeded. The chief symptoms were suppression of stools and violent pain in the abdomen, quite unattended with vomiting, and at first without any remarkable change in the pulse. The preparation which is in Mr. Bullin's possession, is interesting. It is to be presumed that, in this example, the disease and stricture of the colon had been the original complaint.

In the treatment of this disease, bleeding, to lessen the inflammation that might be brought on, and quicksilver, to remove the cause, have been recommended.

Quicksilver would have little effect either in one way or the other, if the introsusception were downwards; for it is to be supposed that it would easily make its way through the innermost contained gut, and if it should be stopped in its passage, it would, by increasing its size, become a cause (as before observed) of assisting the disease. In cases of the retrograde kind, quicksilver, assisted by the peristaltic motion, might be expected to press the introsusception back; but even under such circumstances it might get between the containing and inverted gut into the angle of reflection, and, by pushing it farther on, increase the disease it is intended to cure.—(*J. Hunter.*)

Every thing that can increase the action of the intestine downwards, is to be particularly avoided, as tending to increase the peristaltic motion of the outer containing gut, and thus to continue the disease. Medicines can never come into contact with the outer fold, and, having passed the inner, can only act on the outer farther down, and therefore cannot immediately affect that portion of the outer which contains the introsusception; but we must suppose that whatever affects or comes into contact with the larger portion of the canal, so as to throw it into action, will also affect by sympathy any part that may escape such application. Mr. Hunter therefore recommends emetics, with the view of inverting the peristaltic motion of the containing gut, which will have a tendency to bring the intestines into their natural situation.

If this practice should not succeed, it might be proper to consider it as a retrograde introsusception, and by administering purges, endeavour to increase the peristaltic motion downwards.—(*J. Hunter.*)

I cannot agree with Mr. Langstaff, that it is to be regretted Hunter's name should be affixed to the foregoing proposal, or that it is an absurd one; for purgatives and emetics were only recommended to increase the peristaltic action, the former downwards, the latter upwards, according as the supposed nature of the case might require, and this effect they certainly would have, notwithstanding vomiting is an early and constant symptom of the disease, and an insuperable constipation an equally invariable attendant. The method, I allow, however, is not very hopeful, and may sometimes be frustrated by the formation of adhesions. According to Mr. Langstaff, the *Recherches Historiques sur la Gastrotomie dans le Cas de Volvulus, par M. Hevin*, contain many interesting facts, and a great deal of sound reasoning. There we find a very ample discussion of the question concerning the propriety of opening the abdomen, in order to disentangle the introsuscepted intestine; a proposal which M. Hevin very properly condemns.

If the equivocal and uncertain nature of the symptoms of volvulus were not sufficient to deter us from undertaking an operation, which, under the most favourable circumstances, could not fail to be extremely difficult, and imminently hazardous to the patient, the state of the invaginated parts would entirely banish all thoughts of such an imprudent attempt; for the different folds of the intestine often become agglutinated to each other, so that they can hardly be withdrawn after death (*Simpson, Edinb. Med. Essays, vol. 6, Hevin's 4th Obs.; Malcolm, Physical and Lit. Essays, vol. 2, p. 360; Hunter, Med. and Chir. Trans.; and Soemmering in Transl. of Baillie's Morb. Anat.*); nay, the stricture on the introsuscepted part may cause it to inflame, and even mortify.—(*Soemmering.*) It is very clear, that in this state of parts, the operation of gastrotomy would be totally inadmissible, even if the symptoms could clearly indicate the nature of the case, and the affected part could be easily reached and examined.

The forcible injection of glysters was found useless by Dr. Monro, and the agglutination of the parts must produce an insuperable obstacle to the bowels being pushed back by this means. Some have proposed the employment of a long bougie, or a piece of whalebone, to push back the intestine; and this proposal may be adopted when we are furnished with an instrument adapted to follow the windings of the large intestine to its origin in the right ileum, without any risk of perforating the gut in its course.—(*Langstaff.*)

It must be confessed, that both surgery and medicine are almost totally unavailing in the present disease. Yet here, as in many other instances, the resources of nature are exhibited in a most wonderful and astonishing manner, while those of art completely fail. The invaginated portion of intestine sometimes sloughs, and is discharged *per anum*, while the agglutination of the parts preserves the continuity of the intestinal canal. The annals of medicine furnish numerous instances, in which long pieces of gut have been discharged in this manner, and the patient has recovered. Hence, some hope may be allowed under the most unpromising circumstances. In a case related in Duncan's Commentaries, eighteen inches of small intestine were voided *per anum*; vol. 9, p. 278. Three similar instances occur in M. Hevin's Memoir; twenty-three inches of colon came away in one of these, and twenty-eight of small intestines in another. Other cases occur in the Physical and Literary Essays, vol. 2, p. 361: in Duncan's Annals, vol. 6, p. 298; in the Med. Chir. Trans. vol. 2, where Dr. Baillie states that a yard of intestine was voided. The patients did not, however, ultimately survive in every one of these instances.—(*Langstaff, in Edinb. Med. and Surgical Journal.*) A very interesting case, in which a recovery was effected on this principle, and in which from 15 to 18 inches of the ileum were discharged from the anus, was recorded by Mr. Bush last year (1823), in the *Med. and Phys. Journ.*

Langenbeck has recorded an instance, in which a prolapsus of the large intestines protruded half an ell out of the anus. The disease had lasted thirty weeks. Langenbeck made an incision into, or rather through, the protruded inverted bowel, immediately below the sphincter ani. He first divided the inner vascular coat, then the muscular, and lastly the outer coat, with great caution. He now discovered, within the protruded inverted bowel which he had opened, another part of the intestinal canal, which was not yet inverted. He remarked upon it the appendices epiploicæ, and the white shining peritonæal coat. This last portion would also have become inverted, had the disease continued. He next reduced the latter uninverted part, and afterward succeeded in replacing the rest of the protrusion; which did not fall down again when the boy had stools. No bad symptoms immediately followed; but the lad being very weak, survived only eight days.—(See *Bibl. für die Chir. b. 3, p. 756. Gött.* 1811.)

INVERSION OF THE UTERUS.—(See *Uterus, Inversion of.*)

IODINE. The following are the formulæ recommended by Brera:—1. *Tincture of iodine* made by dissolving 48 grains of pure iodine in an ounce of alcohol. The dose for adults is from 5 to 20 drops three times a day. The *tincture* is subject to decomposition, and should therefore be used fresh. Dr. Manson's tincture contains one drachm of iodine in 3 iiss. of rectified spirit. Of this he commonly prescribes 30

minimus thrice a day. Mr. Buchanan puts 3j. of iodine to ℥ iij. of rectified spirit, and prefers the external to the internal use of the medicine, as more efficacious and less likely to create nausea and other unpleasant symptoms. He has often observed, that when desquamation of the cuticle, and great itching followed the external application of the tincture, the parts received more benefit than when the cuticle retained its natural appearance.—(*On Diseased Joints*, *p.* 86.) 2. *Pills of iodine*, made by forming one grain of iodine into two pills, with elder-rob and liquorice root; one to be taken every morning and evening. 3. *Iodine ointment*, made by mixing a drachm of pure iodine with an ounce of lard, or half a drachm of hydriodate of potass with an ounce and a half of lard; of the former about a scruple, of the latter a bit about as large as a filbert, may be rubbed on the part to which it is intended to be applied. Dr. Manson's ointment has 3 ss. of the hydriodate to an ounce of lard. 4. *Solution of hydriodate of potass*, formed by dissolving 36 grs. of the hydriodate in an ounce of distilled water: it is given in the same dose as the tincture. 5. *Solution of the ioduretted hydriodate of potass*, made by dissolving 36 grs. of the hydriodate and 10 grs. of pure iodine in 10 drachms of water. The dose, in the beginning of its use, should not be more than 5 or 6 drops three times a day.

From Dr. Keller's statement, in the Revue Méd. for June, 1823, it appears, that the ointment is made stronger in France than that mentioned by Brera, two drachms of the hydriodate being mixed with an ounce of fat.

In administering iodine, care must be taken not to combine it with substances calculated to decompose it, and only to let the patient take it when the stomach is empty. The liquid preparations are generally given by Dr. Coindet in syrup and water. When ill effects arise from its too violent operation, such as pains in the stomach, chest, bowels, defective vision, loss of sleep, palpitations, tremours, convulsions, &c., or even inconveniences of a less dangerous kind, the medicine should be immediately discontinued. A strict regimen, copious mucilaginous drinks, the tepid bath, and sometimes bleeding, are necessary. It is hardly necessary to observe, that the use of iodine requires a great deal of caution, as several cases have happened in which the patients were poisoned with it.—(See *Ed. Med. Journ. vol.* 23, *p.* 225, *&c.*) When the bronchocele, or other tumour, is also in too great a state of irritation from the medicine, fomentations, poultices, and leeches are indicated.

Iodine has obtained considerable reputation for its efficacy in bronchocele, scrofula, various chronic tumours, diseased joints, enlargements of the breast, bursæ mucosæ, testicle, &c.—(See *Brera's Saggio Clinico sull' Iodio, e sulle differenti sue combinazioni, Padua*, 1822; *J. R. Coindet, on the Effects of Iodine, in Bronchocele and Scrofula; a Translation of his three Memoirs, by Dr. J. R. Johnson, Lond.* 1821. *Magendie's Formulary, ed.* 2, *Lond.* 1824. *Medical Researches on the Effects of Iodine in Bronchocele, Paralysis, Chorea, Scrofula, Fistula Lachrymalis, Deafness, Dysphagia, White Swelling, and Distortions of the Spine, by Alex. Manson*, 8*vo*, *Lond.* 1825. *An Essay on a New Mode of Treatment for Diseased Joints, &c. by Thomas Buchanan*, 8*vo*, *Lond.* 1828.)

IRIS, PROLAPSUS OF. A small tumour, formed by the protrusion of a portion of the iris through an opening in the cornea. It is sometimes named *staphyloma of the iris*.

The causes of this complaint are such wounds and ulcers of the cornea as make an opening of a certain extent into the anterior chamber of the aqueous humour, and such violent contusions of the eyeball as occasion a rupture of the cornea. If the edges of a wound in this situation, whether accidental, made for the purpose of extracting the cataract, or evacuating the matter of hypopyum, be not brought immediately afterward into reciprocal contact, or continue not sufficiently agglutinated together to prevent the escape of the aqueous humour from the anterior chamber, regularly as this fluid is reproduced; the iris, drawn by its continual flux towards the cornea, glides between the lips of the wound, becomes elongated, and a portion of it gradually protrudes beyond the cornea, in the form of a small tumour. The same thing takes place whenever the eyeball unfortunately receives a blow, or is too much compressed by bandages, during the existence of a recent wound of the cornea. Also, if the patient should be affected, in this circumstance, with a spasm of the muscles of the eye, with violent and repeated vomiting, or with strong and frequent coughing, a prolapsus of the iris may be caused. When an ulcer of the cornea penetrates the anterior chamber, the same inconvenience happens more frequently than when there is a recent wound of that membrane; for the solution of continuity in the cornea, arising from an ulcer, is attended with loss of substance, and, in a membrane so tense and compact as this is, the edges of an ulcer do not admit of being brought into mutual contact.

In purulent and scrofulous ophthalmy, where a minute ulceration of the cornea often occurs, the extensive implication of the iris, and consequent strabismus, Mr. R. Welbank conceives, might be prevented by the early application of belladonna; and "perhaps (he adds), where the ulceration is remote from the circumference of the cornea, and very small, the iris may be kept wholly disengaged, till processes of reparation prevent the risk of protrusion."—(*Note in Frick's Treatise on Diseases of the Eye, ed.* 2, *p.* 6. 11.)

The little tumour is of the same colour as the iris, viz. brown or grayish, being surrounded at its base by an opaque circle of the cornea, on which membrane there is an ulcer, or a wound of not a very recent description.

As it usually happens that the cornea is only penetrated at one part of its circumference by a wound or ulcer, only one prolapsus of the iris is commonly met with in the same eye. But if the cornea should happen to be wounded or ulcerated at several distinct points, the iris may protrude at several different places of the same eye, forming an equal number of small projecting tumours on the surface of the cornea. Scarpa has seen a patient who had three very distinct protrusions of the iris on the same cornea, in consequence of three separate ulcers penetrating the anterior chamber, one in the upper and two in the lower segment of the cornea.

If, says Scarpa, the delicate structure of the iris, the great quantity of blood-vessels which enter it, and the numerous nervous filaments which proceed to be distributed to it as a common centre, be considered, the nature and severity of those symptoms may be readily accounted for, which are wont to attend this disease, however small the portion of the iris projecting from the cornea may be, even if no larger than a fly's head. The hard and continual frictions to which this delicate membrane is then exposed, in consequence of the motions of the eyelids, together with the access of air, tears, and gum to it, are causes quite adequate to the production of continual irritation; and the blood which tends to the point of the greatest irritation, cannot fail to render the projecting portion of the iris much larger, almost directly after its protrusion, than it was at the moment of its first passing through the cornea. Hence, it soon becomes more incarcerated and irritated. In the incipient state of the disease, the patient complains of a pain similar to what would arise from a pin penetrating the eye; next he begins to experience, at the same time, an oppressive sensation of tightness or constriction over the whole eyeball. Inflammation of the conjunctiva and eyelids, a burning effusion of tears, and an absolute inability to endure the light, successively take place. As the protruded portion of the iris drags after it all the rest of this membrane, the pupil assumes of mechanical necessity an oval shape, and deviates from the centre of the iris towards the seat of the prolapsus. The intensity of the pain, produced by the inflammation, and other symptoms, do not, however, always continue to increase.

Indeed, old protrusions of the iris are often noticed, where, after the disease has been left to itself, the pain and inflammation spontaneously subside, and the tumour becomes nearly insensible.

In the early stage, some direct the iris to be replaced by means of a whalebone probe; and, in case of difficulty, a dilatation of the wound or ulcer of the cornea to be made proportioned to the exigency of the case, as is done for the return of a strangulated intestinal hernia. Others only recommend stimulating the prolapsed portion of the iris, with the view of making it contract and shrink into the eye; or suddenly exposing the eye affected to a very vivid light, in the

belief that, as the pupil then forcibly contracts, the piece of the iris, engaged between the lips of the wound, or ulcer of the cornea, will rise to its proper place. However, Scarpa represents all such methods as absolutely useless, and even dangerous. Supposing it were possible, by such attempts, to reduce the iris to its proper situation without tearing or injuring it, still the aqueous humour would escape again through the wound or ulcer of the cornea, so that the iris, when replaced, would fall down the moment afterward, and project from the cornea in the same way as before the operation. Hence, though Scarpa admits that the prolapsus of the iris is a serious accident, he argues, that as surgery has no means of suppressing at once, or at least of suspending, the escape of the aqueous humour through a wound, much less through an ulcer of the cornea, when either exceeds certain limits, the prolapsus of the iris, far from being an evil in such unfavourable circumstances, is rather useful, and, perhaps, the only means of preventing the total loss of the organ of sight; for the flap of the iris insinuates itself, like a plug, between the edges of the wound or ulcer of the cornea, and thus completely prevents the exit of the aqueous humour.

Here I ought to observe, that Scarpa's unlimited condemnation of the plan of ever attempting to replace the iris is contrary to the advice delivered by Beer, as may be seen by referring to the article *Cataract*, where the treatment of the protrusion of the iris after the operation of extraction is noticed. And even with respect to the prolapsus of the iris from ulceration making its way through the cornea, Beer distinctly states, that a recent prolapsus of this kind, formed in the second still existing stage of ophthalmy, may not only be lessened by proper treatment, calculated to produce a quick cicatrization of the ulcer, but the iris may be again completely removed from the cornea, without any adhesion to the edge of the ulcer taking place.—(*B.* 2, *p.*63.) But where the prolapsus of the iris remains, as a consequence of previous inflammation of the eye, Beer confesses, that it cannot be cured without a partial adhesion of the iris to the cornea being left, and a dense scar on the latter membrane in the situation of the protruded iris.—(*Vol. cit. p.* 66.)

In conformity to Scarpa's principles, there are two principal indications in the treatment of the recent prolapsus of the iris The first is, to diminish, as speedily as possible, the exquisite sensibility in the protruded part of the iris; the other is gradually to destroy the projecting portion of this membrane, to such a depth as shall be sufficient to prevent the little tumour from keeping the edges of the wound or ulcer of the cornea asunder, and retarding cicatrization. The adhesion, however, which connects the iris with the inside of the cornea, must not be destroyed.

For fulfilling these indications, touching the portion of the iris projecting from the cornea with the oxygenated muriate of antimony, or with what is more expeditious and convenient, the argentum nitratum, is recommended, so as to form an eschar of sufficient depth. And in order that this operation may be effected with quickness and precision, it is necessary that an assistant, standing behind the patient's head, should support the upper eyelid with Pellier's elevator; and that the patient should keep his eye steadily fixed on one object.

While the assistant gently raises the upper eyelid, the surgeon must depress the lower one with the index and middle fingers of his left hand; and, with the right, he is to be ready to touch the little prominence formed by the iris with the argentum nitratum, scraped to a point like a pencil. This is to be applied to the centre of the little tumour, until an eschar of sufficient depth is formed. The pain which the patient experiences at this moment is very acute; but it subsides as soon as the eye is bathed with warm milk. The caustic, in destroying the projecting portion of the iris, destroys the principal organ of sensibility, by covering it with an eschar of sufficient depth to protect the part affected from the effect of the friction of the eyelids, and from coming into contact with the air and tears. This is the reason, not only why the sense of pricking and constriction in the eye abates after the application of the caustic, but also why the inflammation of the conjunctiva undergoes a considerable diminution, as well as the burning and copious effusion of tea

As in the case of ulcer of the cornea, these advantages only last while the eschar remains adherent to the little tumour formed by the iris; when it falls off, as it usually does two or three days after the use of the caustic, all the above-mentioned symptoms are rekindled, with this difference, that they are less intense and acute than they were previously, and the tumour of the iris is not so prominent as it was before the caustic was applied. When these symptoms make their appearance, the surgeon must once more have recourse to the argentum nitratum, with the precautions explained above; and he is to employ it a third, and even a fourth time, as occasion may require, until the prominent portion of the iris is sufficiently reduced to a level with the edges of the wound or ulcer of the cornea, and no obstacle is left to the granulating process and complete cicatrization.

There is a certain period, beyond which the application of caustic to the protruded iris becomes exceedingly dangerous, though at first it may have been highly beneficial; beyond which the eschar, which previously soothed the pain, exasperates it, and reproduces the inflammation of the conjunctiva, in almost as vehement a degree as in the beginning of the disease. This appears to Scarpa to be the case whenever the surgeon continues to employ the caustic, after the little tumour of the iris has been destroyed to a level with the external edges of the wound or ulcer of the cornea, and the application begins to destroy the granulations just as they are originating. Hence, as soon as the surgeon perceives that the part of the iris projecting from the cornea is sufficiently lowered, and that the application of the argentum nitratum, far from allaying, only irritates the disease, he must desist entirely from using the caustic, and be content with introducing between the eye and eyelids, every two hours, the collyrium zinci sulphatis with the mucilage of quince seeds. Every morning and evening, Janin's ophthalmic ointment, weakened with a double or triple proportion of lard, is to be applied. If the stimulus of such local remedies should not disturb the work of nature, the ulcer gradually diminishes, and heals in the course of a fortnight.

The adhesion which the projecting part of the iris contracts to the internal margin of the wound or ulcer of the cornea during the treatment, continues the same after the perfection of the external cicatrix, and of course during the rest of the patient's life. Hence, even after the most successful treatment of the prolapsus of the iris, the pupil remains a little inclined towards the place of the scar in the cornea, and of an oval figure. The change in the situation and shape of the pupil, however, causes little or no diminution of the patient's faculty of discerning distinctly the smallest objects, and is much less detrimental to the sight than one inexperienced in these matters might conceive; provided the scar on the cornea be not too extensive, nor situated exactly in the centre of this membrane. In the first case, the sight is the less obstructed, as the pupil, which, on the first occurrence of the prolapsus, was narrow, oblong, and drawn considerably towards the wound or ulcer, gradually enlarges, and forms a less contracted oval. As soon as the wound is completely healed, the pupil tends, in some degree, to occupy its former situation in the centre of the cornea; a fact also noticed by Richter.

According to Scarpa, the recision of the protrusion with scissors can only be practised with success when the iris has contracted a firm adhesion to the internal edge of the wound or ulcer of the cornea; and more especially in that ancient prolapsus of the iris, in which the projecting portion of the iris has become with time almost insensible, hard, and callous, with its base strangulated between the edges of the wound or ulcer of the cornea, and besides being adherent to them, having also a slender pedicle. Scarpa indeed has seen an incarcerated one fall off of itself.

In such circumstances, the recision of the old prolapsus of the iris is not attended with the least danger; for, after removing with a stroke of the scissors that prominent portion of the iris which has already contracted internal adhesions to the ulcerated margin of the cornea, so as to reduce it to a level with the external edges of the ulcer, there is no hazard of renewing the effusion of the aqueous humour, or giving an opportunity for another piece of the iris to be protruded. One or two applications of the argentum nitra-

-hum suffice afterward for the production of granulations on the ulcer of the cornea, and the formation of a cicatrix. But it is not so in the treatment of the recent prolapsus of the iris, which has no adhesions to the internal edges of the wound or ulcer of the cornea.

In four subjects affected with recent prolapsus of the Iris, after Scarpa had removed, with a pair of convex-edged scissors, a portion of that membrane projecting beyond the cornea, of about the size of a fly's head, he found, on the ensuing day, that a new portion of the iris, not less than the first, had made its way through the ulcer of the cornea, and that the pupil was very much contracted, and drawn considerably farther towards the ulcer of the cornea. These circumstances took place notwithstanding the wound was touched immediately afterward with the argentum nitratum. Hence Scarpa apprehends, that if he were ever to divide such a little tumour again, it would reappear, and always with an additional protrusion of the iris, and a farther distortion of the pupil. The advantage of caustic in the recent sensible prolapsus of the iris, and the use of scissors only in old callous cases, agree also with the directions given both by Beer and Mr. Travers.—(*Lehre von den Augenkr. b.* 2, *p.* 68; *and Synopsis*, *p.* 280.)

There is a particular species of prolapsus, much less frequent, indeed, than that of the iris, but which does occur, and, in Scarpa's opinion, is very improperly termed by modern oculists, "*prolapsus of the tunic of the aqueous humour.*"—(*Janin, Pellier, Guérin, Gleize, &c.*) Neither do his sentiments upon this subject agree with those of Beer, whose explanation of the nature of the case is noticed in the article *Cataract.* We shall there see that it is a case which he terms *ceratocele*, and which he thinks arises from a yielding of the inner layers of the cornea, in consequence of the outer ones not having united. And in his second vol. p. 59, he has given a description of the same kind of disease from the support of the outer layers of the cornea being destroyed by ulceration. This is a point on which the most experienced men differ so much, that it is difficult to reconcile their statements. Dr. Vetch seems to have full reliance upon the accuracy of the accounts of a protrusion of the membrane of the aqueous humour.—(*Treatise on Diseases of the Eye*, *p.* 54, *&c.*) Mr. Travers inclines to Beer's view of the subject, and details reasons for doubting that the vesicle is a distinct texture: "its appearance corresponds accurately to that of the innermost lamella of the cornea."—(*Synopsis*, *&c. p.* 116.)

It is, says Scarpa, a transparent vesicle, filled with an aqueous fluid, and composed of a very delicate membrane, projecting from a wound or ulcer of the cornea, much in the same way as the iris does under similar circumstances. Scarpa has several times seen this transparent vesicle, full of water, elongating itself beyond the cornea, shortly after the operation for the extraction of the cataract, and sometimes also in consequence of an ulcer of the cornea, especially after rescinding a prolapsed portion of the iris.

The generality of oculists believe, that this little transparent tumour consists of the delicate, elastic, diaphanous membrane which invests the inner surface of the cornea, and is described by Descemet and Demours. "As soon as the membrane lining the cornea (they say) is exposed by the wound or ulcer of the latter, and the delicate pellicle can no longer resist the impulse of the humours pressing behind it, it is necessitated to yield gradually, to become elongated, and to project from the wound or ulcer of the cornea, exactly in the form of a pellucid vesicle." But, says Scarpa, how remote this theory is from the truth must be manifest: 1. The delicate and elastic pellicle described by Descemet and Demours, is not separable by any artifice from the inner surface of the cornea, except near where the cornea and sclerotica unite. Since these protruded vesicles make their appearance in practice at every point of the cornea, and even at its very centre, where the above pellicle is certainly neither separable nor distinct from the compact texture of the cornea, it may at least be asserted that the tunic of the aqueous humour does not in every instance constitute the transparent vesicle in question. 2. It is a well-known fact, that this vesicular pellucid prolapsus happens more frequently after the extraction of the cataract than on any other occasion. In this case, since the tunic of the aqueous humour has certainly been divided to afford an exit to the crystalline, no one can be of opinion, that the transparent vesicle which protrudes from the cornea after this operation ought to be attributed to the distention and protrusion of the tunic of the aqueous humour. 3. If, in cases of ulcers of the cornea, the transparent vesicle should sometimes appear after the recision of the prolapsus of the iris, it is obvious, that if it consisted of the tunic of the aqueous humour, it ought invariably to appear before the prolapsus of the iris. 4. Should the surgeon remove the protruded vesicle to a level with the cornea by a stroke of the scissors, a small quantity of limpid water is seen to ooze out, at the moment when the incision is made, without any part of the aqueous humour escaping from the anterior chamber. This inconvenience would be inevitable were the protruded vesicle in question formed by the delicate elastic pellicle, which is said to invest the inner surface of the cornea. Besides, the little transparent tumour disappears when the incision is made; but often another one, exactly similar to what was cut off, is found in the very same place the following day. Had the little transparent tumour been composed of the tunic of the aqueous humour, elongated out of the wound or ulcer of the cornea, it could not at all events have been reproduced at the same part of the cornea.

It is clear to Scarpa, that the pretended prolapsus of the tunic of the aqueous humour is, strictly speaking, only a forcible protrusion of a portion of the vitreous humour, which, from too much pressure being made on the eye, either at the time of the operation, or afterward, or from a spasm of the muscles of the eye, insinuates itself between the edges of the wound after the extraction of the cataract, and projects in the form of a transparent vesicle. The same thing also happens after ulcers of the cornea, whenever the aqueous humour has escaped, and a portion of the vitreous humour is urged by forcible pressure towards the ulcer facing the pupil; or whenever an elongated piece of the vitreous humour, after the recision of a prolapsed portion of the iris, passes by a shorter route than through the pupil, between the lips of the ulcer of the cornea. At length we understand why in both these instances a transparent vesicle forms, even after the recision of the tunic of the aqueous humour or ulceration of the cornea; and why it very often reappears in the same place, though it has been cut away to a level with the cornea. It is because one or more cells of the vitreous humour, constituting the transparent vesicle, are succeeded after their removal by other cells of the same humour, which glide between the lips of the wound or ulcer of the cornea into the same situation.

The treatment of this species of prolapsus consists in removing the transparent vesicle projecting from the wound or ulcer, by means of a pair of curved scissors with convex edges, and bringing the edges of the wound of the cornea immediately afterward into perfect apposition, in order that they may unite together as exactly as possible. But when there is an ulcer of the cornea, as soon as the vesicle is removed, the sore must be touched with the argentum nitratum, so that the eschar may resist any new prolapsus of the vitreous humour, and at the same time dispose the ulcer of the cornea to granulate and heal.

If, in some particular cases, the vesicle should not project sufficiently from the wound or ulcer of the cornea to be included in the scissors, the same object may be accomplished by puncturing the tumour with a lancet or couching needle; for when the limpid fluid which it contains is discharged, the membrane forming it shrinks within the edges of the wound or ulcer of the cornea, and no longer hinders the union of the former or the cicatrization of the latter.

Should the transparent tumour reappear in the same situation the day after its recision or puncture, it is right to repeat one of these operations, and to adopt farther measures for maintaining the edges of the wound of the cornea in contact; or, if it should be an ulcer, the eschar must be made to adhere more deeply to its bottom and sides, so as form a greater obstacle to the escape of the vitreous humour. In these circumstances, the surgeon must take all possible care to obviate such causes as have a tendency to propel the vitreous humour towards the wound or ulcer of the cornea; particularly too much pressure on the eyelids, spasms of the muscles of the eye, coughing, sneezing, efforts

at stool, and other similar ones; and care must also be taken to check the progress of inflammation.

Scarpa has seen a prolapsus of the choroid coat, two lines from the union of the cornea with the sclerotica, in the inferior hemisphere of the eye. It was preceded by a small abscess, the consequence of severe ophthalmy. The treatment consisted in applying the argentum nitratum several times to the projecting portion of the choroides, until it was consumed, and reduced to a level with the bottom of the ulcer of the cornea. The part then healed. The eye remained, however, considerably weakened, and the pupil afterward became nearly closed.—*Scarpa sulle Principali Malattie degli Occhi, Venezia*, 1802. *Richter's Anfangs. der Wundarzneykunst, b.* 3; *Von den Vorfalle der Regenbogenhaut. IRITIS. Inflammation of the iris.—See OPHTHALMY.

ISCHU'RIA. (From ἴσχω, to restrain; and οὖρον, the urine.) A suppression or stoppage of the urine.

The distinction between a *suppression* and *retention* of urine is practical and judicious. The former most properly points out a defect in the secretion of the kidneys; the latter, an inability of expelling the urine when secreted.—(*Hey.*)

The first disease is not very common, is named *ischuria renalis*, or *suppression of urine*, and belongs to the province of the physician; the second is an exceedingly frequent disorder, is named *ischuria vesicalis*, or *retention of urine*, and its treatment is altogether surgical.—(See *Catheter*, and *Urine, Retention of.*)

ISSUE signifies an ulcer, made designedly by the practitioner, and kept open a certain time, or even the patient's whole life, for the cure or prevention of a variety of diseases.

The physician, in his practice, has frequent occasion to recommend the making of an issue, and the surgeon finds it a principal means of relief in several important cases, as for instance, white swellings, disease of the hip-joint, caries of the vertebræ, &c. Many persons are never in health, or, at least, fancy themselves always ill, unless they have an issue formed in some part of their body or another. The making of an issue, indeed, is not unfrequently considered as an imitation of nature, who, of her own accord, often forms ulcers and abscesses in various parts of the body (as is not uncommonly conjectured) for the purpose of discharging pernicious humours, whereby people are supposed to be freed from grievous disorders, and have their health preserved. The humoral pathologists were excessively partial to these notions, which, at the present time, will be found by every experienced practitioner to influence the mass of mankind, and render the formation of issues more common than perhaps is consistent with the better established principles of medical science. Few old subjects will allow a sore of long standing to be dried up (as the expression is), without requiring the surgeon immediately afterward to make an issue for them. When an ulcer has existed a great length of time, the constitution, may possibly become so habituated to it, that the health may really suffer from its being healed. "I have often (says the experienced Dr. Parry) seen various thoracic affections, as pulmonary consumption, asthma, carditis, or hydrothorax, arise from the spontaneous, or artificial cure of ulcers, perpetual blisters, or fistulæ."—(*Elements of Pathology, &c. p.* 386.) Asthmatic complaints, severe headaches, &c. are frequently observed to follow the cicatrization of an old ulcer; but whether they would have happened if an issue had been made in time, is a question difficult of positive determination; for many persons with old ulcers are not prevented from suffering from asthma and headache. The plan of making an issue, however, is commendable both as rational and exempt from danger. Whatever may be the solidity of the theories, which have been offered by medical writers, in regard to issues the practitioner who has his eyes open cannot fail to see the benefit often derived from such means; and if there be any unquestionable facts in medicine and surgery, we may confidently set down among them the frequent possibility of relieving one disease by exciting another of a less grievous and more curable nature.

There are two ways of making an issue: one is with a lancet, or scalpel; the other with caustic.

The place for the issue being fixed upon, the surgeon and his assistant are to pinch up a fold of the integuments, and, with a lancet or knife, make in them an incision of sufficient size to hold a pea, or as many peas as may be thought proper. The pea or peas are then to be placed in the cut, and covered with a piece of adhesive plaster, a compress, and bandage. The peas, first inserted, need not be removed for three or four days, when suppuration will have begun; but the issue is afterward to be cleaned and dressed every day, and have fresh peas put into it. The preceding is the ordinary method of making such issues as are intended to contain only one or two peas.

When the issue is to be larger, which is generally proper in cases of diseased vertebræ, white swellings, &c., the best plan is to destroy a portion of the integuments with caustic. The caustic potassa, blended with quicklime, is mostly preferred for this purpose. The situation and size of the issue having been determined, the surgeon is to take care, that the caustic does not extend its action to the surrounding parts. With this view, he is to take a piece of adhesive plaster, and having cut a hole in it, of the exact shape and size of the issue intended to be made, he is to apply it to the part. Thus the plaster will defend the adjacent skin from the effects of the caustic, while the uncovered portion of integuments, corresponding to the hole in the plaster, is that which is to be destroyed. The caustic is to be taken hold of with a bit of lint, or tow, and its end, having been a little moistened with water, is to be steadily rubbed upon the part of the skin where the issue is to be formed. The frictions are to be continued, till the whole surface, intended to be destroyed, assumes a darkish corroded appearance. The caustic matter may now be carefully washed off with some wet tow. The plaster is to be removed, and a linseed poultice applied. As soon as the eschar is detached, or any part of it is loose enough to be cut away, without pain or bleeding, the peas are to be inserted and confined in their proper place with a piece of adhesive plaster. Some use beans for the purpose; others beads, which answer very well, and have the advantage of serving for any length of time, when washed and cleaned every day. If the issue is of a longitudinal shape, the peas, beans, or beads may be more easily kept in their places, when a thread is passed through them.

Issues ought always to be made, if possible, in a situation where the peas will not be much disturbed by the ordinary motions of the body, nor interfere with the action of muscles. The interspaces between the margins and insertions of muscles are deemed the most eligible places. Thus, issues in the arm are usually made just at the inferior angle of the deltoid muscle, by the side of the external edge of the biceps. In the lower extremities, issues are often made at the inner side of the thigh, immediately above the knee, in a cavity that may be readily felt there with the fingers. Sometimes issues are made upon the inside of the leg, just below the knee. For the relief of certain affections of the head or eye, the nape of the neck is commonly selected as a good situation. In caries of the vertebræ, they are made on each side of the spinous processes. In cases of diseased hips, they are formed in a depression just behind and below the trochanter major. When the nature of the disorder does not particularly indicate the situation for the issue, the arm should be preferred to the leg, as issues upon the upper extremities, especially the left arm, are much less annoying, than upon either of the lower limbs.

The great art of keeping an issue open, for a long

while, consists in maintaining an equal and effectual pressure upon the peas, by which means, they are confined in their places, little depressions are made for them, and the granulations hindered from rising. Compresses of pasteboard and sheet-lead will often be found highly useful. This plan is the surest one of preventing the issue from healing, and the most likely to save the patient all the severe and repeated suffering, which the fresh application of the caustic, or the use of stimulating powders, in order to renew the sore and repress the fungous flesh, unavoidable occasions.

There is a method of making issues with the caustic made into a sort of paste, which is laid upon the part left uncovered by the adhesive plaster. It seems to me to be a more tedious and painful plan, and I do not recommend it.

It has been suspected that the pain arising from the caustic might be lessened, by mixing opium with the application; but the idea seems not at all probable; the destruction of a part of the skin must inevitably cause considerable pain, with whatever substance it is produced, and opium itself, so far from being likely to diminish the agony, is itself a violent stimulus, whenever it comes into contact with the exposed extremities of the nerves.

[The inconvenience arising from pea issues, and the difficulty of keeping them open for a length of time, as is often needful, have long since suggested to surgeons a variety of other methods of making issues, less troublesome to the patient and his medical attendant. Some of these expedients are here alluded to, and I will add another which I have adopted for a number of years most satisfactorily, and for which I am indebted to Dr. P. K. Rogers of William and Mary College, Virginia. The issue is made by the simple process of rubbing the skin with a stick of the potass. pur. vulgo lapis infernalis, until as much of the surface is destroyed as is necessary. The process is effected in about five minutes, if constantly applied; and its perfection is known by the black and horny aspect of the eschar. Its property may be instantly neutralized if too violent, by washing the part with vinegar, and the effect ceases. A poultice is then applied, and in eight or ten days there is a slough comes off; when it may be dressed with savin ointment, which will keep it open indefinitely.—*Reese.*]

J

JAW-BONE, AMPUTATION OF CONSIDERABLE PORTIONS OF THE LOWER. This operation, which is one of the achievements of modern surgery, was first performed, by Dr. Mott, in America; and it has since been done by Dupuytren, Graefe, Lallemand, Syme, M'Clennan, Lizars, Crampton, Cusack, Hodgson, [Wegner, Randolph, J. K. Rogers, Reese,] and others.

[The operation of amputation of the lower jaw, one of the most formidable in surgery, was doubtless *first* performed by Dr. Mott, although Mr. Cooper, in his "First Lines," has attributed it to Dupuytren, and the "Philadelphia editor" (*stat nomine umbra*) of the last edition, ascribes it to Dr. Deadrick of Tennessee. It is passing strange, that surgical writers cannot distinguish between removing a "*part* of the lower jaw" and that part the *symphisis*, and the amputation of the bone *at the articulation*. They may *write* these two operations among their synonymes, but I apprehend if they encounter the latter operation on the living subject, they will never again proclaim their identity. *Palmam qui meruit, ferat.* Dr. Mott is not only the *first*, but the *only* surgeon, who has amputated the bone successfully at the articulation, except (since) Dr. Cusack, of Dublin. The removal of a *part* of this bone has been very often performed, even in this country; and although I am one of those who have removed a part of this bone successfully, and that part extending from the bicuspid tooth of the left side to the angle of the right, yet it would be presumptuous to insinuate that the difficulty and hazard of removing it at the joint is not a vastly different and more formidable operation. And, reasoning à priori, it may be safely affirmed, that had not Dr. Mott demonstrated its practicability, many of those who now discourse very gravely of the *facility* of its performance, and even presume to give instructions as to the mode of operating, and condemn certain steps in his operation, would themselves shudder at proposing to remove this bone at the joint, even after the carotid artery was secured.

The propriety of tying the carotid, as a preliminary step in this operation, or its necessity at least, may be questioned. Dr. Mott has since performed the same operation without tying the carotid, and by experience is convinced that it would be unnecessary in cases in which he would formerly have thought it indispensable. There may be cases of the disease for which this operation is necessary, in which, from the extension of the disease, and the state of the vessels, it would be unsafe to proceed to the operation without tying the carotid; in general, however, it may be dispensed with. I recollect some years since, in removing a tumour from the neck, I commenced by tying the carotid, and from the hemorrhage I encountered immediately afterward, in extirpating the tumour, I was well satisfied that no advantage whatever had been derived from the ligature to that vessel; and I have never since thought it needful to repeat it; although I have often removed tumours of the jaw and neck, for which it is said to be necessary. But to tie this vessel at one time, and then wait a few days before proceeding to the operation, is the climax of surgical folly; and it is mortifying to hear this course recommended by very high authorities. Experience will convince any operator that the circulation will be as fully restored in a few hours, as though his ligature were in his pocket.

In amputating the lower jaw, it has been found that the subsequent management of each individual case has been a work requiring much skill and attention. More than one of the cases which have resulted unfavourably have been attributed to the effort of deglutition, which became necessary before the parts had united. Indeed, the wound made by the surgeon is so extensive, and the adaptation of the parts so important to success, that many days ought to elapse before even the saliva should be suffered to pass into the stomach. Hence the patient is directed to lie on the side, so that the saliva may flow out of the mouth, instead of collecting in the throat.

The patient on whom I operated in April, 1828, was in frail health, and 60 years of age. At the time of the operation he was so reduced by starvation and loss of sleep, consequent upon an osteo-sarcomatous tumour of the jaw, which obstructed deglutition, and impaired his respiration, that I would not have ventured upon its removal, if I had designed to deprive him of food even for six days, as surgeons direct. I knew there would be a necessity for food and drink of cordial and nutritious character; and accordingly half an hour after the operation, I introduced the *stomach-tube* of elastic gum, and thus poured into the stomach half a pint of wine and water. It was passed, without inconvenience, several times a day for the first week, and water, coffee, chocolate, soup, and other fluids thus introduced, until the eighth day, when he could swallow with ease; entire union having already taken place, from the quiet state in which the parts had been kept. I apprehend the use of the stomach-tube, in these cases, will remove much of the hazard attending them, and be found greatly to promote the rapid recovery of the patients.—(See note on article *Osteo-Sarcoma.*)—*Reese.*]

JOINTS, DISEASES OF. The joints are subject to numerous diseases, which are more or less dangerous, according to their particular nature. Like all other parts, the joints are liable to inflammation and abscesses; their capsules frequently become distended with an aqueous secretion, and the disease termed *hydrops articuli* is produced; but the most important of all their morbid affections are the cases which a few years ago were indiscriminately called *white swell-*

ings, *scrofulous joints*, and the *disease of the hip-joint*. Here, as Mr. Brodie remarks, the same name has been frequently applied to different diseases, and the same disease has received different appellations. And confusion with respect to the diagnosis always gives rise to a corresponding confusion with respect to the employment of remedies. Although, says he, diseases in their advanced stage extend to all the dissimilar parts of which the joints are composed, such is not the case in the beginning. Here, as elsewhere, the morbid actions commence, sometimes in one and sometimes in another texture, differing in their nature, and, of course, requiring to be differently treated, according to the mechanical organization and vital properties of the part in which they originate.—(See *Pathological and Surgical Obs. on Diseases of the Joints*, *p.* 2, 8*vo. Lond.* 1818.) It was this idea, which led Mr. Brodie to trace by dissection the exact parts in which several of the principal diseases of the joints commence, and how much light and discrimination his successful investigations have produced, it is needless for me here to insist upon, as his merit will long be appreciated by every surgeon, who recollects the perplexity and ignorance which prevailed only a few years ago in this very interesting branch of surgery.

Wounds.—By the wound of a joint, surgeons mean a case where the capsular ligament is penetrated or divided. The injury is often accompanied with a division of the lateral or other ligaments, and sometimes also with that of the cartilages and bones. That the capsular ligament is wounded may generally be learned by the introduction of a probe, and frequently by a discharge of a transparent viscid fluid, called the synovia. But as a similar discharge may proceed from mere wounds of the bursæ mucosæ, we might form an erroneous judgment, were we unacquainted with the situation of these little membranous bags. I am, at this present time, (Aug. 1829,) attending a man, whose leg was attacked with erysipelas in consequence of a superficial laceration of the skin of the knee by a fall. A small abscess formed below the patella; and, ever since it burst, a considerable quantity of fluid, resembling white of egg, and evidently secreted by the neighbouring bursa, has been daily discharged with the pus. Boyer has seen several cases, in which a fluid, resembling synovia, was discharged from wounds of the sheaths of tendons.—(See *Traité des Maladies Chirurg. t.* 4, *p.* 408.) Here the advice which I have given in another place (see *Wounds of the Abdomen*), respecting the temerity of being too officious with the probe, is equally important, inasmuch as the rough introduction of this instrument into a large joint, like the knee, would be likely to excite inflammation of the synovial membrane, and a train of dangerous and even fatal consequences, while the information gained by such employment of the probe is of little use; because whenever a wound is suspected to reach into the capsular ligament, exactly the same treatment should be followed as if the joint were positively known to be penetrated.

Notwithstanding simple wounds, even of large joints, often heal favourably without any bad symptoms, this is not constantly the case, and the records of surgery furnish many examples in which the most alarming and fatal consequences ensued.—(See *Hunter's Commentaries*, *part* 1, *p.* 69.) When properly treated, punctured wounds of the joints (says Boyer) are not in general attended with danger; but, as some of these wounds, which were apparently quite simple, have been followed by very bad symptoms, and even death, we should always be extremely circumspect in the prognosis.—(See *Traité des Mal. Chir. t.* 4, *p.* 409.) The treatment consists in endeavouring to heal the injury by the first intention; in applying cold lotions; forbidding all motion of the part; and employing bleeding and other antiphlogistic remedies.

Baron Boyer relates two cases of punctured wounds of the elbow joint, which healed up in a few days, without any unfavourable symptom. He acknowledges, however, that these accidents do not always go on so well, and that the consequences are sometimes perilous.

Simple incised wounds present only one indication; viz. that of healing the part by the first intention. At the moment of the accident, some of the synovia is discharged, indicating that the capsular ligament is wounded. Should this circumstance not have been noticed at first, the surgeon may see the synovia flow out again, if he move or press upon the joint. But, in making this examination, the greatest gentleness should be used, lest the irritation of the capsular ligament be increased. When the wound is large, and there is no considerable thickness of soft parts, the articular surfaces are exposed to view.

The prognosis of an incised wound of a joint is not generally unfavourable, when the edges have been immediately brought together, the cavity of the joint has not been long exposed, and blood is not extravasated in it. This last danger is also exaggerated, as will be noticed in speaking of collections of blood in joints. With these exceptions, says Boyer, the wound may heal as readily as if the joint were not opened; and he has cited several facts in proof of this statement. Its truth is also confirmed by the success which attends operations practised for the purpose of extracting cartilaginous substances from the knee. Nay, very bad cases sometimes recover under judicious management, even though the joint be large, and abscesses follow. Thus I saw, in St. Bartholomew's Hospital, in the year 1820, two examples of compound fractures of the patella, where the opening in the capsule was so large, that the finger could readily pass into the cavity of the joint, yet, after large abscesses, a great deal of fever, and separation of bone, the patients recovered with stiff joints. But I would advise surgeons not to let any facts of this kind prejudice their judgment in the treatment of gunshot wounds of the large joints, where, in the circumstances elsewhere explained (see *Amputation* and *Gunshot Wounds*), amputation is the safest practice. In a sabre or cut wound, the principal object is to heal the wound by the first intention. The rest of the treatment consists in using every possible means for the prevention of inflammation, by perfect quietude of the part, the use of cold applications, &c.

Let it be remembered, however, that wounds of the joints do not always heal in the above favourable manner. Even among those cases which appear the most slight and simple, there are but too many which are followed by such aggravated symptoms as either prove fatal or occasion a necessity for amputation. And in other instances of a less grievous description, when the patient is cured, the termination of danger is not without an anchylosis, by which the motion and functions of the joint are permanently destroyed.

The experienced Mr. Hey has noticed wounds of the joints, and made some pertinent remarks on the subject. He states, that, in these cases, the utmost care should be taken to *prevent* inflammation, "Upon this circumstance chiefly depends a successful termination. I have seen (says he) many large wounds of the great joints healed without the supervention of any dangerous symptoms, where due care has been taken to prevent inflammation; while injuries, apparently trifling, will often be followed by a train of distressing and dangerous consequences, where such care has been neglected. It is generally easier to prevent inflammation in the joints after a wound, than to arrest its progress when once begun. I speak now of inflammation affecting the capsular ligament. A slight degree of redness and tenderness in the integuments only is of little consequence; but when the capsular ligament becomes inflamed, the formation of abscesses, attended with a high degree of fever, and ultimately a stiffness of the joint, are the common consequences, if the life of the patient is preserved."—(See *Practical Obs. in Surgery*, *p.* 354, *edit.* 2.)

For facts in confirmation of the foregoing account, I particularly refer to several cases recorded in this last publication, *p.* 355, *et seq.*, and by *Boyer*.—(*Traité des Mal. Chir. t.* 4, *p.* 426, *&c.*)

When the large joints, particularly the knee, are wounded, the stomach is frequently very much affected. I formerly saw, under the care of Mr. Best of Newbury, a man who, in his occupation as a wheelwright, happened to give himself a wound, by which one side of the knee was laid open; a good deal of constitutional disturbance and of inflammation and suppuration ensued; but what particularly struck me, was the manner in which the stomach was disordered.

In speaking of cartilaginous substances in the joints I shall have occasion to advert again to the danger attendant on wounds of these parts; and the same fact is still farther considered in the articles *Amputation*, *Dislocations*, *Fractures*, and *Gunshot Wounds* in

which last part of the Dictionary the sentiments of Baron Larrey, and other writers on military surgery, are laid before the reader.

Inflammation of joints, if we exclude from consideration specific cases, may be said usually to be the consequence of a contusion, sprain, wound, or some other kind of injury: but with respect to the inflammation of the synovial membrane, as described by Mr. Brodie, no cause is so frequent as the application of cold, and hence he explains the frequency of this disease in the knee, and its rarity in the hip and shoulder, which are covered by a thick mass of flesh. As a late writer observes, the inflammation arising from a wound is infinitely the most severe after it has once commenced.—(*James on Inflammation*, *p.* 157.)

The inflamed joint shows the common symptoms of inflammation: viz. preternatural redness, increased heat, throbbing, pain, and swelling, while the constitution is also disturbed by the common symptoms of inflammatory fever. It deserves notice, however, that in these cases the constitutional symptoms are often exceedingly severe, and the pulse is more frequent, and less full and strong, than when parts more disposed to return to a state of health are affected. The inflammation first attacks some part of the capsular ligament, and very quickly spreads over its whole extent, as usually happens in all inflammations of smooth serous membranes.

The capsules of the joints are naturally not very sensible; but, like many other parts similarly circumstanced, they often become acutely painful when inflamed. The complaint is accompanied with an increased secretion of the synovia, which becomes of a more aqueous, and of a less albuminous quality, than it is in the healthy state. Hence, it is not so well calculated for lubricating the articular surfaces, and preventing the effects of friction, as it is in the natural condition of the joint; a circumstance which may explain why a grating sensation is often perceived on moving the patella.

The capsular ligaments, like other parts, are frequently thickened by inflammation, and sometimes coagulating lymph being effused on their internal surfaces, organized cartilaginous or osseous bodies are formed within the joints.

It has been explained by Mr. Brodie, that the usual consequences of inflammation of the synovial membrane, or capsular ligament, are: 1, a preternatural secretion of synovia; 2, an effusion of coagulating lymph into the cavity of the joint; 3, a thickening of the synovial membrane, a conversion of it into a substance resembling gristle, and an effusion of coagulable lymph, and probably of serum, into the cellular structure, by which it is connected with the external parts. The same gentleman has seen several cases where, from the appearance of the joint and the symptoms, there was every reason to believe that the inflammation had produced adhesions of the reflected folds of the membrane to each other: and, in dissection, he has occasionally observed adhesions which might have arisen from inflammation at some former period. "These effects of inflammation of the synovial very much resemble those of inflammation of the serous membranes. There are, however, some points of difference. In the former, I have reason to believe that suppuration rarely takes place independently of ulceration; but this is a frequent occurrence in the latter. Inflammation of the peritoneum or pleura, though very slight in degree, and of very short duration, terminates in the effusion of coagulable lymph; but it is only violent or long-continued inflammation which has this termination in the membranes of joints."—(*Med. Chir. Trans. vol.* 4, *p.* 216.)

When the inflammation attains a high pitch, an abscess may occur in the capsular ligament, which at length ulcerates, and the pus makes its way beneath the skin, and is sooner or later discharged through ulcerated openings.

An abscess rarely takes place in an important articulation in consequence of acute inflammation, without the system being also so deranged that life itself is imminently endangered. Severe febrile symptoms always afflict the patient, and occasionally delirium and coma taking place, death itself ensues. Two rapidly fatal cases of ulceration of the synovial membrane, where matter had formed within it from a sprain of the hip, and a contusion of the shoulder, are recorded by Mr. Brodie.—(See *Pathol. Chir. Obs. p.* 65.)

In these cases, the inflammatory fever is very quickly converted into the hectic: indeed, when an abscess has taken place in a large joint, in consequence of acute inflammation, hectic symptoms almost immediately begin to show themselves, and the strong actions of the common inflammatory fever suddenly subside.

Local consequences, even worse than those above described, may follow inflammation of a joint. As the layer of the capsular ligament reflected over the cartilages of the articulation is often inflamed, the cartilages themselves may have the inflammation communicated to them. Parts of a cartilaginous structure, being very incapable of bearing the irritation of disease, often ulcerate, or, in other words, are absorbed, so as to leave a portion or the whole of the articular surface of the bones completely denuded of its natural covering. At length the heads of the bones themselves inflame and become carious; or the consequence may be anchylosis. Mr. Brodie has seen some cases in which there was extensive destruction of the cartilages, apparently in consequence of neglected inflammation of the synovial membrane; but he believes that, in most cases where ulceration of the cartilage is combined with such inflammation, the former is the primary affection, and the latter takes place subsequently, in consequence of the formation of an abscess within the joint.—(*Pathol. and Surg. Obs. &c. p.* 17.) According to Mr. Brodie, who speaks chiefly of the inflammation which begins in the synovial membrane itself, and is not communicated to it from other textures, the disease very seldom attacks young children, but is frequent in adult persons, the reverse of what happens in some other diseases of the joints.

The inflammation of the capsular ligament, or synovial membrane, frequently assumes the chronic form, and is then very often confounded with other more serious maladies, under the general appellation of white swelling. The disease often arises from cold, and hence is more common in the knee and ankle than in the hip or shoulder. It may also arise from the immoderate use of mercury, and, in particular constitutions, from rheumatism and general debility of the system. In these instances, it often leaves one joint and attacks another; and it is less severe, and less disposed to produce effusion of coagulating lymph, or a thickened state of the membrane, than when it is apparently a local disease.—(*Brodie, in Med. Chir. Trans. vol.* 4, *p.* 218.) In the latter case, the disorder is more likely to assume a severe character, and may be of long duration, leaving the joint with its functions more or less impaired, and occasionally terminating in its total destruction. The following are the chief symptoms of the complaint, pointed out by Mr. Brodie. At first, although some pain is felt over the whole joint, the patient refers it principally to one spot, and it is not at its height before the end of a week or ten days. Sometimes, even at this period, the pain is trifling, but sometimes it is considerable, and every motion of the joint is distressing. In a day or two after the commencement of the pain, the joint is affected with swelling, which at first arises entirely from a collection of fluid in its cavity, and in the superficial joints an undulation may be distinguished. However, after the inflammation has prevailed some time, the fluid is rendered less perceptible, either in consequence of the synovial membrane being thickened, or the effusion of lymph; and the more solid the swelling is the more is the mobility of the joint impaired. The form of the diseased joint does not correspond to that of the heads of the bones; but as the swelling is chiefly caused by the distention of the synovial membrane, "its figure depends in a great measure on the situation of the ligaments and tendons, which resist it in certain directions, and allow it to take place in others. Thus, when the knee is affected, the swelling is principally observable on the anterior and lower part of the thigh," where there is only a yielding cellular structure between the extensor muscles and the bone. It is also often considerable in the spaces between the ligament of the patella and the lateral ligaments, because at these points the fatty substance is propelled outwards by the collection of fluid. In the elbow, the swelling occurs principally above the olecranon, under the extensor muscles of the forearm; and in the ankle, it is between the lateral ligaments and the tendons in front of the joint. In the hip and shoulder, where the disease is less frequent, the fluid cannot be felt, but the

swelling is perceptible through the muscles. In the beginning of this disease in the hip, a fulness both in the groin and nates may be remarked; but afterward the nates become flattened, and the glutæi wasted from want of use. The pain is usually confined to the hip, but Mr. Brodie has seen cases in which it was also referred to the knee. It may be discriminated from the case in which the cartilages of the hip are ulcerated, by observing, that *the pain is more severe in the beginning than in the advanced stage of the disease;* it never amounts to the excruciating sensation felt in the other disease; and it is aggravated by motion, but not by pressing the cartilaginous surfaces against each other. The wasting of the glutæi is also preceded by a fulness of the nates. After the inflammation has subsided, the fluid is absorbed, and the joint frequently regains its natural figure and mobility; but in the majority of cases, stiffness and swelling remain, and the patient continues very liable to relapse, the pain returning, and the swelling being augmented, whenever the patient exposes himself to cold, or exercises the limb a great deal. In cases where the synovial membrane is thickened, a slow kind of inflammation sometimes continues in the part, notwithstanding the fluid has been absorbed, and the principal swelling has subsided, the disease at length extending to the cartilages, suppuration taking place, and the articular surfaces being completely destroyed. According to Mr. Brodie, in this advanced stage, the history of the disease, and not its present appearance, is the only thing by which one can learn whether the primary affection was inflammation of the synovial membrane or ulceration of the cartilages. Though such is the most common character of inflammation of the synovial membrane, it is admitted, that its nature is sometimes more acute, exhibiting the symptoms mentioned at the beginning of this section.—(See *Pathol. and Surg. Obs. p.* 21, *&c.*) It is remarked by Mr. Wilson, that, when coagulable lymph is effused, the whole of it does not always adhere to the inflamed surface, but some of it forms flakes, which float in the fluid within the joint, in masses large enough to be sometimes felt through the capsular ligament. In other instances the lymph becomes solid, adheres to the inside of the synovial membrane, and becomes vascular. The surface of this adventitious coating is sometimes smooth; but occasionally it forms thick projecting masses, of different degrees of thickness and length, and so numerous as to conceal every part of the original smooth surface of the synovial membrane, as exemplified in a preparation in Windmill-street.—(*On the Skeleton and Diseases of Bones and Joints, p.* 319.)

When inflammation of the synovial membrane has arisen from a protracted or ill-conducted course of mercury, Mr. Brodie recommends a trial of sarsaparilla; and when the disorder is connected with rheumatism, the medicines advised are opium with diaphoretics, preparations of colchicum autumnale, and other usual remedies for rheumatic complaints. In some instances, however, in which several joints were affected, this gentleman has known benefit derived from moderate doses of mercury.—(*P.* 31.) But whether the disease be local, or dependent on the state of the constitution, Mr. Brodie considers topical remedies of most importance.

It will considerably shorten what we have to say concerning the treatment of inflamed joints, to observe, that, in the acute form of inflammation of the synovial membrane, the antiphlogistic plan, in the full sense of the expression, is to be strictly adopted. But as there is a variety of means often adapted to the same purpose, it seems necessary to offer a few remarks on those which lay the greatest claim to our commendations.

There are not many surgical cases in which general and especially topical bleeding is more strongly indicated. The violence of the inflammation, and the strength, age, and pulse of the patient, must determine with regard to the use of the lancet; but the application of leeches may be said to be invariably proper. When the leeches fall off, the bleeding is to be promoted by fomenting the part. The surgeon should daily persist in this practice until the acute stage of the inflammation has subsided. As Mr. Brodie observes, attention should also be paid to the state of the bowels, and saline draughts and diaphoretic medicines be exhibited.—(*Pathol. and Surg. Obs. p.* 32.) In conjunction with this treatment the lotio plumbi acetatis must be employed.

In a few instances, however, the patient seems to derive more ease and benefit from the employment of fomentations and emollient poultices, which, according to Mr. Brodie, is the case when the swelling has been produced rapidly, and is attended with considerable tension. But on this point, as I have remarked in speaking of *inflammation*, the feelings of the afflicted should always be consulted; for if the pain be materially alleviated by this or that application, its employment will hardly ever be wrong.

Nothing more need be said concerning the rest of the treatment proper during the vehemence of the inflammation, as the duty of the surgeon is not materially different from what it is in other cases where organs of importance are inflamed.

As soon as the acute stage of the affection has subsided, the grand object is to remove its effects. These are a thickened state of the capsular ligament and parts surrounding the articulation; a stiffness of the joint, and pain, when it is moved; fluid in the capsule, &c.

At first, as Mr. Brodie has observed, the joint should be kept perfectly quiet, and blood should be several times taken from the part, by means of leeches and cupping. The latter is the method to which the preceding writer gives the preference. The use of cold evaporating lotions is also to be continued until the inflammation has farther abated, when a blister may be applied, and kept open with the savin cerate, or a repetition of blisters kept up, as preferred by Mr. Brodie. "The blisters (he says) should be of considerable size; and if the joint be deep-seated, they may be applied as near to it as possible; but otherwise at a little distance. Thus, when the synovial membrane of the hip is affected, they may be placed on the groin and nates; but when that of the wrist is inflamed, they should be applied to the lower part of the forearm." Mr. Brodie thinks blisters have more effect than any other means in removing the swelling; but, excepting in very slight cases, he very rightly condemns their use unprecedented by the abstraction of blood. After the subsidence of the inflammation, moderate exercise of the joint and stimulating liniments are recommended. The camphor liniment is to be strengthened with the addition of liquor ammoniæ, or tinctura lyttæ, or the following formula, adopted as that to which the above gentleman seems to give the preference. ℞. Olei olivæ ʒiss. acid. sulph. ʒss. M. In this stage of the disease, I find the tincture of iodine possesses considerable efficacy, particularly when blended with the soap liniment in the proportion of ʒj. to ʒij. Mr. Buchanan applies the tincture of iodine to the integuments, and his accounts represent it as being rapidly absorbed from the surface of the skin, and acting very powerfully in dispersing the thickening and induration of various diseases and abscesses of the joints. Indeed, he prefers such application of iodine to its internal exhibition, and states that its effects are produced without the aid of friction, so that it admits of being employed with advantage even when inflammation is present.—(*Essay on a New Mode of Treatment of Diseased Joints, &c. Lond.* 1828.) Mr. Brodie speaks favourably of the effects of the antimonial ointment, in the proportion of ʒj. of the antim. tart. to ʒj. ung. cetacei. Plasters of gum ammoniac he regards as sometimes useful in preventing relapses. Issues and setons are never serviceable, unless ulceration of the cartilages has begun. For the removal of the remains of the swelling and stiffness, Mr. Brodie joins other writers in praising the efficacy of friction and exercise. The friction may be made with camphorated mercurial ointment, or with powdered starch; but the friction is to be employed with caution, as otherwise it may produce a return of the inflammation. When this happens, it is to be discontinued, and blood taken from the part. On the whole, Mr. Brodie appears to consider friction better adapted to cases where the stiffness depends upon the state of the external parts, than to others where it arises from disease in the joint itself. With respect to the plan of allowing a column of warm water to fall on the part, as suggested by Le Dran, and practised at the watering-places, he allows that it is beneficial, but that it requires the same caution as the employment of friction.—(*Pathol. and Surg. Obs. p.* 30, *&c.*)

I have met with several instances in which lotions, composed of vinegar and muriate of ammonia, sufficed for the removal of the chronic complaints, left after the acute stage of the disorder. The tincture and

ointment of iodine are also valuable applications; and they may be blended with other liniments, which will thus be rendered more efficient.

The severity of the constitutional symptoms is mostly, if not always, greater when the inflammation of a large joint arises from a wound, than when it is the consequence of a bruise or sprain.

Loose Cartilages in Joints.—Hard, roundish, or flattened bodies, mostly of a cartilaginous nature, are sometimes formed within the capsular ligaments, occasioning more or less pain in the affected joints, and a considerable impediment to the freedom of their movements. The disorder, though not noticed by any of the very ancient writers, is far from being uncommon. Paré is the first who speaks of it: he says, that *a hard, polished, white body, of the size of an almond*, was discharged from the knee of a patient, in the year 1558, in which he had made an incision for an *aqueous apostume* (without doubt a hydrops articuli).—(*Lib.* 25, *chap.* 15, *p.* 772.) A hundred and thirty-three years afterward, viz. in 1691, Pechlin published the full details of another case, in which a cartilaginous body was successfully extracted from the knee.—(*Observat. Physico-Med. obs.* 38, *p.* 306.) Dr. A. Monro, in 1726, dissected the knee-joint of a woman, who had been hung, and found in the articulation a cartilaginous body, of the shape and size of a small bean. These were the only examples of the disease known before the year 1736, at which period Mr. Simpson cut out of the knee a similar substance, which he supposed at the time of the operation was only beneath the skin.—(See *Edinb. Med. Essays*, *vol.* 4.) But of late years the disease has been frequently noticed and described, particularly by Bromfield, Hewit, Middleton, Gooch, Ford, Home, Bell, Abernethy, and Brodie, in England; by Henckel, Theden, and Loeffler, in Germany; and by Desault and Sabatier, in France. Hence, as Boyer remarks, it is now as well known, as most others, to which the joints are subject.—(*Traité des Mal. Chir. t.* 4, *p.* 434.)

Such detached and moveable cartilages are not peculiar to the knee, as they occur in other joints; yet they are most frequently met with in the knee, and it is in this joint that they produce symptoms which render them the object of a surgical operation. Morgagni and B. Bell met with them in the ankle; Haller in the joint of the jaw; and Hey in the elbow.

According to Sir Everard Home, these substances are analogous in their structure to bone; but in their external appearance they bear a greater resemblance to cartilage. They are not, however, always exactly of the same structure, being in some instances softer than in others. Their external surface is smooth and polished, and, being lubricated by the synovia, allows them to be moved readily from one part of the joint to another. They seldom remain long at rest while the limb is in motion; and when they happen to be in situations where they are pressed upon with force by the different parts of the joint, they occasion considerable pain, and materially interfere with its necessary motions.

The circumstance of their being loose, and having no visible attachment, made it difficult to offer good conjectures respecting their formation; and according to Sir E. Home, no satisfactory account of their origin had been given when Mr. Hunter made his observations. In the course of his experiments, instituted with the view of proving a living principle in the blood, Mr. Hunter was naturally induced to attend to the phenomena which took place when that fluid was extravasated, whether in consequence of accidental violence or other circumstances. The first change he found to be coagulation; and the coagulum thus formed, if in contact with living parts, did not produce an irritation similar to extraneous matter, nor was it absorbed and taken back into the constitution, but in many instances preserved its living principle and became vascular, receiving branches from the neighbouring blood-vessels for its support; it afterward underwent changes, rendering it similar to the parts to which it was attached, and which supplied it with nourishment. When a coagulum adhered to a surface which varied its position, the attachment was rendered in some instances pendulous, and in others it was entirely broken.

Hence it was easy to explain the mode in which those pendulous bodies are formed, which are sometimes attached to the inside of circumscribed cavities, and the principle being established, it became equally easy for Mr. Hunter to apply it under other circumstances, since it is evident from a known law in the animal economy, that extravasated blood, when rendered an organized part of the body, can assume the nature of the parts into which it is effused, and consequently the same coagulum which in another situation might form a soft tumour, would, when situated on a bone or in the neighbourhood of bone, often form a hard one. The cartilages found in the knee-joint, therefore, appeared to him to originate from a deposite of coagulated blood upon the end of one of the bones, which had acquired the nature of cartilage and had afterward been separated. This opinion was farther confirmed by the examination of joints which had been violently strained, or otherwise injured, where the patients had died at different periods after the accident. In some of these cases there were small projecting parts, preternaturally formed, as hard as cartilage, and so situated as to be readily knocked off by any sudden or violent motion of the joint.—(*Trans. for the Improvement of Med. and Chir. Knowledge*, *vol.* 1.)

Mr. Brodie met with two cases, however, in which the loose bodies were of a different nature, and had a different origin from that referred to by Sir E. Home. Sometimes disease causes a bony ridge to be formed, like a small exostosis, round the margin of the cartilaginous surfaces of the joint. In the two examples alluded to, this preternatural growth of bone had taken place, and, in consequence of the motion of the parts, portions of it had been broken off and lay loose in the cavity of the joint.—(*Med. and Chir. Trans. vol.* 4, *p.* 276.) And in a more recent publication he remarks, that in the majority of cases which he has met with, no inflammation preceded the formation of these preternatural substances, and therefore he thinks it probable that, in some instances, they are generated like other tumours by some different process. He farther observes, that they appear to be situated originally either on the external surface, or in the substance of the synovial membrane, since before they become detached, a thin layer of the latter may be traced over them.—(*Pathological and Surgical Obs. p.* 298.)

One or more of these preternatural bodies may be formed in the same joint. Sir E. Home mentions one instance in which there were three; they are commonly about the size of a horse-bean, often much smaller, and sometimes considerably larger; when very large, they do not give so much trouble to the patient as the smaller kind. A soldier of the 56th regiment had one nearly as big as the patella, which occasioned little uneasiness, being too large to insinuate itself into the moving parts of the joint. Morgagni saw twenty-five in the left knee of an old woman, who died of apoplexy; and Haller met with no less than twenty, in the articulation of the lower jaw. When there are several in the same joint, it is observed, that their size is generally small.—(*Boyer*, *Traité des Mal. Chir. t.* 4, *p.* 436.)

The diagnosis of this disease, as Boyer observes, is seldom attended with any difficulty. When the formation of the extraneous substances follows a fall or blow upon the joint, the complaint begins with a swelling of the surrounding soft parts, and upon the subsidence of this swelling, which lasts for a time more or less long, the presence of the little cartilaginous tumours is indicated by certain symptoms which are peculiar to them. In persons who have had no blow nor fall upon the knee, the disease sometimes commences with a more or less acute pain in the joint, with or without swelling of the surrounding soft parts, and which affection is usually regarded as rheumatism. To these first symptoms, which are common both to cases of foreign bodies in the joints, and other diseases of these parts, are soon added other particular signs, by which the nature of the case is evinced.

As the extraneous bodies are in general free and moveable in the joint, they can easily be made to slip about from one part of the articulation to another; a circumstance which is facilitated by the smoothness of their surface, as well as by the synovia, which is mostly in larger quantity than natural. According to the situation which they happen to occupy, sometimes they produce acute pain; sometimes no pain whatever. When they lodge in a depression where they are not compressed, they cause no pain; and if they could be always kept in this position, their presence would not

be likely to excite any inconveniences. But when they get between the articular surfaces, which in certain postures of the limb come into contact with each other, the following are the effects of the compression. Sometimes the extraneous substance suddenly glides between the condyles of the thigh-bone and head of the tibia, and while it lodges there, excites acute pain in certain directions of the limb, and instantaneous loss of the power of moving the knee. But when it shifts its place again, either naturally or accidentally, during an examination of the affected part, the compression is removed, the pain all at once ceases, and the functions of the joint are as suddenly restored. Most frequently when the extraneous body gets behind the patella, or the ligament of the patella, as the patient is walking, he is compelled to make a sudden stop, and would fall down from the acuteness of the pain if nothing were at hand to save him. Some patients have been observed, however, who experienced no pain in these circumstances. Reimarus mentions a man who suffered great pain and could not move his leg when the extraneous body was at the side of the joint; but was immediately relieved by pushing it under the patella. B. Bell met with cases in which the pain was so violent at the instant when the patients put their legs in certain postures, that fainting was brought on, and they were so afraid of a return of the suffering, that they preferred remaining perfectly quiet to running any risk of causing the pain again. He even asserts, that he had known some persons in whom the least motion of the limb would cause such pain as awoke them out of the deepest sleep. The pain, excited by the situation of the extraneous body between the articular surfaces, recurs at intervals more or less long, and always in consequence of some motion or exertion. Sometimes it ceases directly by the effect of a movement contrary to that which produced it; but most frequently it continues, and then the surrounding soft parts are affected with swelling, which obliges the patient to keep his bed and have recourse to emollient anodyne applications. Sometimes, as I have already noticed, the foreign body lies at a part of the joint where it causes no inconvenience, and makes no pressure on the articular surfaces. In this case all the symptoms have been known to cease for several months, so that the patient imagined himself cured, when suddenly the foreign body was urged by some effort into another situation, where it occasioned a renewal of all the former pain.

The foregoing circumstances afford strong presumptive evidence of the presence of extraneous cartilaginous substances in the joint; but they do not amount to certainty: this can only be acquired by the touch. In handling the knee of the patient, the surgeon feels a hard, prominent substance, which slips about under his fingers and glides under the patella, or the ligament of this bone, and sometimes under the tendon of the extensor muscles of the leg, from one side of the joint to the other. The extraneous body may make its appearance either at the inside or the outside of the articulation; but it most frequently presents itself at the former part, which is the broadest and most sloping, while the capsular ligament there is loosest. Desault met with one instance, in which the capsular ligament and soft parts were so loose that the patient could turn the extraneous substance round and round.

In general, the complaint is not dangerous; but as it is painful, and obstructs or often prevents walking, and usually can be cured only by an operation which has sometimes had fatal consequences, we cannot be too much upon our guard in delivering a prognosis.

It is only in the knee that the disease ever becomes so troublesome as to require an operation, or, indeed, any surgical treatment.

If we except making an incision into the joint, for the purpose of extracting the cartilaginous tumours, we are not acquainted with any certain means of freeing a patient from the inconvenience of the complaint. To this plan, the danger attendant on all wounds of so large an articulation as the knee, is a very serious objection. Middleton and Gooch endeavoured to conduct the extraneous body into a situation where it produced no pain, and to retain it in that position a long time by bandages, under the idea that the cartilaginous substance would adhere to the contiguous parts, and occasion no future trouble. Some will be inclined to think, that no positive conclusion ought to be drawn from the cases brought forward by these gentlemen, because they had no opportunity of seeing their patients again at the end of a reasonable length of time; and we know that loose cartilages in the joints sometimes disappear for half a year, and then make their appearance again. Yet, perhaps, the very circumstance of the patients not applying again, may justify the inference that sufficient relief had been obtained.

However, it should not be concealed that this method was also tried in St. George's Hospital without benefit, and that in one case the pain was increased by it.—(See *Reimarus de Fungo Articulorum*, § 27, 54, *&c.*)

Mr. Hey, aware of the dangerous symptoms which have occasionally resulted from the most simple wounds penetrating the knee-joint, was induced to try the efficacy of a laced knee-cap, and the cases which he has adduced clearly demonstrate, that the benefit thus obtained is not temporary, at least as long as the patient continues to wear the bandage. In one case the method had been tried for ten years, with all the success which the patient could desire. Boyer also made one patient use a knee-cap for a year; after which it was left off, the patient appearing cured. And, in a second instance, the same practitioner tried the plan, which put a stop to the pain, and enabled the patient to walk with ease; but it was not known whether the method was properly continued, as the patient had not latterly been seen.—(*Boyer, Traite des Mal. Chir. t.* 4, *p.* 444.)

Contemplating the evidence upon this point, and the perilous symptoms sometimes following wounds of the knee-joint, I am decidedly of opinion, that the effect of a knee-cap, or of a roller and compress, applied over the loose cartilage, ought generally to be tried before recourse is had to excision. I say generally, because the conduct of the surgeon ought, in such cases, to be adapted to the condition and inclination of the patient. If a man be deprived of his livelihood by not being able to use his knee; if he cannot or will not take the trouble of wearing a bandage; if he be urgently desirous of running the risk of the operation after things have been impartially explained to him; if a bandage should not be productive of sufficient relief; and lastly, if excessive pain, severe inflammation of the joint, a great deal of symptomatic fever, and lameness, should frequently be produced by the complaint (see *Brodie's Pathological and Surg. Obs. p.* 299), I think it is the duty of a surgeon to operate. Under such circumstances I lately removed a loose cartilage of considerable size from a gentleman's knee, without the previous trial of pressure; and the result was perfectly successful. It is very certain that success has generally attended the operation; but small as the chance is of losing the limb, and even life, in the attempt to get rid of the disease, since the inconveniences of the complaint are, in most cases, very bearable, and are even capable of palliation by means of a bandage, endangering the limb and life in any degree must seem to many persons contrary to the dictates of prudence. At all events, we must agree with Boyer, that, as the laced knee-cap can do no harm, we ought always to make trial of it, and never perform the operation except when pressure does not answer, and the return of frequent and violent pain makes the employment of the knife necessary.—(See *Traité des Mal. Chir. t.* 4, *p.* 445.)

I am ready to allow, with M. Brochier, that the danger attendant on wounds of the large joints, has always been exaggerated in consequence of ancient prejudices.—(*Desault's Journ. vol.* 2.) But, making every allowance for the influence of prejudice, a man must be very skeptical indeed who does not consider the wound of so large a joint as the knee attended with real cause for the apprehension of danger. At the end of Mr. Ford's case (*Med. Obs. and Inquiries, vol.* 5), we read on the subject of cutting loose cartilages out of the knee: "The society have been informed of several cases in which the operation has been performed; some, like this, have healed up without any trouble; others have been followed by violent inflammation, fever, and death itself." A case was lately published, in which the patient very nearly lost his life from suppuration in the knee-joint after this operation.—(See *Kirby's Cases, p.* 75.) In the same work, reference is also made to two other cases, which actually had a fatal termination (*p.* 82); and even in Mr. Kirby's own instance, the recovery was not effected with-

ont the entire loss of the motions of the knee. An example, in which the patient died after the operation, in St. Bartholomew's Hospital, must be fresh in the recollection of many students.

As the disorder is often attended with a degree of heat and tenderness in the articulation; as the danger of the operation is, in a great measure, proportioned to the subsequent inflammation; and as much of the danger is at once removed if the wound unite by the first intention; the advice to keep the patient in bed a few days before operating, to apply leeches and cold saturnine lotions to the knee during the same time, and to exhibit beforehand a saline purgative, is highly prudent.

I shall next introduce an account of the plan of operating, as described by several of the best modern surgeons.

As these loose bodies cannot always be found, no time can be fixed for the operation; but the patient, who will soon become familiar with his own complaint, must arrest them when in a favourable situation, and retain them there till the surgeon can be sent for.

"Before the operation, the limb should be extended upon a table in a horizontal position, and secured by means of assistants; the loose cartilages are to be pushed into the upper part of the joint above the patella, and then to one side: the inner side is to be preferred, as in that situation only the vastus internus muscle will be divided in the operation. Should there be several of these bodies, they must be all secured, or the operation should be postponed till some more favourable opportunity, since the leaving of one will subject the patient to the repetition of an operation not only painful but attended with some degree of danger.

"The loose bodies are to be secured in the situation above mentioned by an assistant; a task not easily performed while they are cut upon, from their being incubrated by the synovia; and if allowed to escape into the general cavity, they may not readily, if at all, be brought back into the same situation.

"The operation consists in making an incision upon the loose cartilage, which it will be best to do in the direction of the thigh, as the wound will more readily be healed by the first intention. If the skin is drawn to one side previously to making the incision, the wound through the parts underneath will not correspond with that made in the skin, which circumstance will favour their union. The incision upon the cartilage must be made with caution, as it will with difficulty be retained in its situation if much force is applied. The assistant is to endeavour to push the loose body through the opening, which must be made sufficiently large for that purpose; but as this cannot always be done, the broad end of an eyed probe may be passed under it so as to lift it out, or a sharp-pointed instrument may be struck into it, which will fix it to its situation, and bring it more within the management of the surgeon.

"The cartilages being all extracted, the cut edges of the wound are to be brought together, and, by means of a compress of lint, not only pressed close to one another, but also to the parts underneath, in which situation they are to be retained by sticking plaster, and the uniting bandage.

"As union by the first intention is of the utmost consequence after this operation, to prevent an inflammation of the joint, the patient should remain in bed with the leg extended, till the wound is perfectly united, or at least all chance of inflammation at an end."—(*Home in Trans. for the Improvement of Med. and Chir. Knowledge, vol.* 1, *p.* 239, *&c.*)

In one instance, Desault proceeded in the following manner: the surgeon, after relaxing the capsular ligament by extending the leg, brought the extraneous body on the inside of the articulation against the attachment of the capsular ligament, and secured it in this situation between the index finger and thumb of the left hand, while an assistant drew the integuments forwards towards the patella. The parts covering this extraneous body were now divided by an incision one inch in length, and its extraction accomplished by pushing it from above downwards, and raising it inferiorly with the end of the knife. This substance, on examination, was found similar in colour to the cartilages that cover the articular surfaces: it was three quarters of an inch in length, six lines and a half in width, and three lines in thickness; its surfaces were smooth, one concave and the other convex: its circumference irregular, disseminated with red points, forming small depressions; the inside was ossified, the outside of a cartilaginous texture. As soon as the substance was extracted, the assistant let go the integuments which he had drawn forwards; they consequently returned to their natural situation on the inner side of the knee-joint, in such a manner that the external wound in the integuments was situated more inwards than the one in the capsular ligament. Two advantages were procured by this means; on the one hand, air was prevented from penetrating into the articulation; and on the other, the floating portion of capsular ligament, retained inwards by the skin, was more likely to attach itself to the condyle, in case it did not unite to the other portion of the capsule divided near its attachment. The edges of the wound were brought into contact by means of the uniting bandage; dry lint and compresses were applied, and retained on the part by a slight bandage; and the limb was kept in a state of extension.—(*Desault's Journal, t.* 2.) According to Mr. Abernethy, the inner surface of the internal condyle of the os femoris presents an extensive and nearly a plain surface, which terminates in front and at its upper part by an edge which forms a portion of a circle. If the points of the finger be firmly pressed upon this edge so as to form a kind of line of circumvallation round these (cartilaginous) bodies, they cannot pass into the joint in this direction, nor can they recede in any other on account of the tense state of the internal lateral ligament. Here these substances are near the surface, and may be distinctly felt; and they may be exposed by simply dividing the integuments, fascia, and the capsule of the joint.

In an interesting case which Mr. Abernethy relates, the integuments of the knee were gently pressed towards the internal condyle, and the fingers of an assistant applied round the circular edge of the bone. The integuments were gently drawn towards the inner hamstring, and longitudinally divided immediately over the loose substance, to the extent of an inch and a half. This withdrawing of the integuments from their natural situation was designed to prevent a direct correspondence of the external wound to that in the capsule of the joint: for when the integuments were suffered to regain their natural position, the wound in them was nearer to the patella than the wound in the capsule. The fascia which covers the joint having been exposed by the division of the integuments, it was divided in a similar direction, and nearly to the same extent. The capsule is now laid bare, and gently divided to the extent of half an inch, where it covered one of the hard substances which suddenly slipped through the opening, and by pressing gently upon the other it was also discharged. The bodies thus removed were about three quarters of an inch in length, and half an inch in breadth. They had a highly polished surface, and were hard like cartilage. The fluid contained in the joint was pressed towards the wound, and about two ounces of synovia were discharged. The wound of the integuments was then gently drawn towards the patella, and accurately closed with sticking plaster.—(*Surgical Observations*, 1804.)

When there are several extraneous cartilaginous bodies in the joint operated upon, the surgeon ought to extract them all through the same wound, if it can be done without producing too much irritation of the capsular ligament, and they will admit of it. But frequently only one can be made to present itself at a time, or can be easily extracted. Each little tumour will then require a separate operation, which is a far safer plan than disturbing the part by long and repeated attempts to extract them all at once.—(*Boyer, Traité des Mal. Chir. t.* 4, *p.* 448.) The surgeon is also often obliged to make his incision at a particular point, because at no other can the extraneous substance be fixed. A case confirming all these latter observations was lately published by Dr. Clarke.—(See *Méd. Chir. Trans. vol.* 5, *p.* 67.) In this instance the operation was thrice performed upon the same knee-joint with perfect success. Mr. Brodie also extracted five loose cartilages, by three different operations, without any subsequent unpleasant symptoms, although the patient appears to have been previously subject to repeated attacks of severe inflammation of the joint.—(*Pathological and Surg. Obs. p.* 299.)

On the preceding subject, some observations and two successful operations have been lately published by Baron Larrey.—(See *Mémoires de Chir. Militaire, t.* 2, *p.* 421, *&c.*) With the exception of a few wrong theories, he appears to have given a fair account of the disease.

Hydrops articuli signifies a collection of serous fluid in the capsular ligament of a joint. The knee is more subject than other joints to dropsical disease, which has been known, however, to affect the wrist, ankle, and shoulder joints.—(*Boyer, Traité des Mal. Chir. t.* 4, *p.* 456.)

Mr. Russell adopts the opinion that some cases of this kind are venereal, and others scrofulous; but the doctrine does not rest upon any solid foundation. Hydrops articuli generally arises from contusions, rheumatism, sprains, exposure to severe cold, the presence of extraneous cartilaginous bodies in the joint, and in general from any thing which irritates the capsular ligament; and, as already explained, it is a common attendant on inflammation of the synovial membrane; the complaint also sometimes follows fevers; but in most instances it is purely a local affection, quite independent of general debility.—(*Boyer, t.* 4, *p.* 467.)

Hydrops articuli presents itself in the form of a soft tumour; circumscribed by the attachments of the capsular ligament; without change of colour in the skin; accompanied with a fluctuation; it is indolent, and very little painful; causing hardly any impediment to the motion of the joint; yielding to the pressure of the finger, but not retaining any impression, as in œdema. The swelling does not occupy equally every side of the joint, being most conspicuous where the capsular ligament is loose and superficial. In the wrist, it occurs at the anterior and posterior parts of the joint, but especially in the former situation, while it is scarcely perceptible at the sides. In the ankle it is more apparent in front of the malleoli than any where else; and in the shoulder it does not surround the joint, but is almost always confined to the forepart of it, and can only be seen in the interspace between the deltoid and great pectoral muscles.

In the knee-joint, which is the common situation of hydrops articuli, the tumour does not occur behind the articulation; but at the front and sides. Behind, the capsular ligament is too narrow to admit of being much distended with the synovia; while in front and laterally it is broad, so that it can there yield considerably in proportion as the quantity of fluid increases. The swelling is at first circumscribed by the attachments of the capsular ligament; but in consequence of the accumulation of fluid, it afterward exceeds these limits above, and spreads more or less upwards between the thigh bone and the extensor muscles of the leg, which are lifted up by it. Boyer has seen it reach to the upper third of the thigh. The swelling is irregular in shape: it is most prominent where the capsular ligament is wide and loose, and it is in some measure divided longitudinally into two lateral portions, by the patella, the ligament of the patella, and the tendon of the extensor muscles of the leg; all which parts the synovia raises, and pushes forwards, though in a much less degree than the capsular ligament. Of these lateral portions, the internal is broadest and most prominent, because the part of the capsule between the patella and edge of the internal condyle being larger than that situated between the patella and edge of the external condyle, yields in a greater degree to the distending fluid. The motions of the leg, which are generally little interrupted by this disease, make a difference in the shape and consistence of the swelling. In flexion, the tumour becomes harder, tenser, and broader, and more prominent at the sides of the knee-pan, which is somewhat depressed by its ligament. In extension, the tumour is softer, and the fluctuation plainer.

In order to feel distinctly the fluctuation, which is one of the best symptoms of the disease, the ends of two or three fingers should be placed on one side of the swelling, while the opposite side is to be struck with the end of the middle finger of the other hand.

The patella being pushed forwards, away from the articular pulley, is very moveable, and, as it were, floating. When it is pressed backwards, while the leg is extended, it can be felt to move a certain way, before it meets with the resistance of the articular pulley. And on the pressure being discontinued it immediately separates from this part again.

By such symptoms, hydrops articuli may easily be distinguished from other diseases of the joints, from tumours of the bursa mucosa under the extensor tendons of the leg; from ganglions in front of the knee-pan; from rheumatism, œdema, &c.

The prognosis is most favourable when the swelling is recent and small, and has been quick in its progress. On the contrary, when the tumour is of long standing and large, the effused fluid thick and viscid, and the synovial membrane thickened, the removal of the fluid by absorption, and the restoration of the parts to their natural state, will be more slow and difficult. The worst case is that which is complicated with disease of the capsular ligament, cartilages, and bones.

The cure of the above-described dropsical affection of the joints depends upon the absorption of the effused fluid. And when the case is combined with acute or chronic inflammation of the synovial membrane, the treatment is the same as that already recommended for those particular forms of disease. When inflammation subsides, the absorption of the fluid is sometimes altogether spontaneous, and it may always be promoted by friction, by rubbing the joint with camphorated mercurial ointment, the ointment or tincture of iodine, the soap liniment, containing 3 j. of the tincture of iodine in every two oz. of it, and particularly by the employment of blisters.

The operation of a blister may be materially assisted with a moderately tight bandage. Among other effectual means of cure, we may enumerate frictions with flannel impregnated with the fumes of vinegar, electricity, and the exhibition of mercurial purgatives. When hydrops articuli occurs during the debility consequent to typhoid and other fevers, the complaint can hardly be expected to get well before the patient regains some degree of strength.

As, however, hydrops articuli is generally quite a local disease, Boyer contends that it should be chiefly treated with topical remedies; and he sets down diuretics, sudorifics, hydragogues, &c. as improper or inefficient.—(*Op. cit. p.* 467.) He is strongly in favour of repeated blisters, both for the prevention and cure of the disease.

Circumstances do not often justify the making of an opening into the joint; but excessive distention, in some neglected cases, might certainly be an urgent reason for such an operation. Also, if the complaint should resist all other plans of treatment, and the irritation of the tumour greatly impair a weak constitution, the practice would be justifiable. An interesting example of this kind is related by Mr. Latta.—(*System of Surgery, vol.* 2, *p.* 490.)

It is best to make the opening in such a way that the wound in the capsular ligament after the operation will not remain directly opposite the wound in the skin. For this purpose, the integuments are to be pushed to one side, before the surgeon divides them.—(*Encyclopédie Méthod. part Chir. art. Hydropisie des Jointures.*)

The operation is not always successful, being sometimes followed by alarming symptoms, which either end fatally, or occasion a necessity for amputation. The fluid also generally collects again, and as the synovial membrane is mostly thickened, it often inflames, and suppuration in the joint ensues. Hence, when hydrops articuli originates from rheumatism; when it is recent, indolent, and not large; and when it does not seriously impair the functions of the joint; Boyer recommends the operation not to be done. But he sanctions its performance when the disease is combined with extraneous cartilaginous bodies in the joint; or when it is very considerable, and attended with severe pain and impairment of the functions of the joint.—(*Op. cit. t.* 4, *p.* 473.)

Collections of Blood in Joints.—Most systematic writers speak of this kind of case, though it must be uncommon. Tumours about the joints, composed of blood, and set down in numerous surgical works as extravasations within the capsular ligaments, are generally on the outside of them.

Were blood known to be undoubtedly effused in a large articulation, however, no man would be justified in making an opening for its discharge. No bad symptoms are likely to result from its mere presence, and the absorbents will, in the end, take it away. If an incision were made into the joint, the coagulated state

of the extravasated blood would not allow such blood to be easily discharged.

The best plan is to apply discutient remedies; lotion of vinegar, spirits of wine, and muriate of ammonia for the first three or four days; and afterward, friction with camphorated liniments may be safely adopted.

Mr. Hey relates a case in which the knee-joint was wounded, and blood insinuated itself into the capsular ligament; yet, though the occurrence could not be hindered, no harm resulted from the extravasation, which was absorbed without having created the smallest inconvenience.—(*Practical Obs. in Surgery, p.* 354.)

White Swelling.—The white swelling, or spina ventosa, as it was at one time not unfrequently called, in imitation of the Arabian writers, Rhazes and Avicenna, has been a name indiscriminately applied to many diseases, which differ widely in their nature, curability, and treatment. Wiseman was the first who used the term white swelling; and if the expression did not confound together complaints of very different kinds, not much fault could be found with it, because it unquestionably conveys an idea of one mark of some of these distempers, which is, that notwithstanding the increase of size in the joint, the skin is generally not inflamed, but retains its natural colour.—(*Pott.*)

The name therefore appears objectionable only inasmuch as it has tended to prevent the introduction of a sufficient number of well-founded and necessary distinctions. Systematic writers have generally been content with a distinction into two kinds, viz. *rheumatic* and *scrofulous*.

The last species of the disease they also distinguish into such tumours, as primarily affect the bones, and then the ligaments and soft parts; and into other cases in which the cartilages, ligaments, and soft parts become diseased, before there is any morbid affection of the bones.

Mr. Brodie has endeavoured to form a more correct classification of the different complaints to which the term white-swelling is applied; and his descriptions are valuable, because confirmed by extensive observation and numerous dissections. With respect to the disease beginning in the ligaments, if the capsular ligaments be put out of consideration, it is, as this gentleman observes, a rare occurrence, and he has never met with a case in which the fact was proved by dissection.—(*Pathol. and Surgical Obs. p.* 7.)

1. The first case is inflammation of the synovial membrane, as described in the foregoing pages, especially that form of the disease which often arises from cold, and constitutes the disease formerly often termed a rheumatic white-swelling.

2. Another form of disease, ordinarily comprised under the general name of white-swelling, has been particularly described by Mr. Brodie: the disease originates in the synovial membrane, which loses its natural organization, and becomes converted into a thick, pulpy substance, of a light brown, and sometimes of a reddish brown colour, intersected by white membranous lines, and from ¼ to ½ of an inch, or even more than an inch, in thickness. As this disease advances, it involves all the parts of which the joint is composed, producing ulceration of the cartilages, caries of the bones, wasting of the ligaments, and abscesses in different places. The complaint has invariably proved slow in its progress, and sometimes has remained nearly in an indolent state for many months, or even for one or two years; but (says Mr. Brodie) "I have never met with an instance in which a real amendment was produced; much less have I known any in which a cure was effected."—(See *Medico-Chir. Trans. vol.* 4, *p.* 220, *&c.*) The whole or nearly the whole of the synovial membrane has always been found affected; though if a very early examination were made, Mr. Brodie conceives that this might not be the case; and in one example he found only a half of the membrane thus altered, while the rest was of its natural structure.—(*Pathol. and Surg. Obs. p.* 94.) This gentleman farther acquaints us, that the preceding affection of the synovial membrane is rarely met with except in the knee; that he has never known an instance of it in the hip or shoulder; that it is peculiar to the synovial membrane of the joints; that he has never known an instance of it in other serous membranes, nor even in the synovial membranes, which constitute the bursæ mucosæ and sheaths of tendons; and that it generally takes place in young persons, under, or not much above, the age of puberty. In fact, Mr. Brodie has not met with more than one instance in which it occurred after the middle period of life. Mr. Hodgson, of Birmingham, it seems, has met with one example of it in the ankle; and another in one of the joints of the fingers. "In the origin of this disease, there is a slight degree of stiffness and tumefaction, without pain, and producing only the most trifling inconvenience. These symptoms gradually increase: at last, the joint scarcely admits of the smallest motion, the stiffness being greater than where it is the consequence of simple inflammation. The form of the swelling bears some resemblance to that in cases of inflammation of the synovial membrane, but it is less regular. The swelling is soft and elastic, and gives to the hand a sensation as if it contained fluid. If only one hand be employed in making the examination, the deception may be complete, and the most experienced surgeon may be led to suppose there is a fluid in the joint when there is none; but, if both hands be employed one on each side, the absence of fluid is distinguished by the want of fluctuation.

"The patient experiences little or no pain until abscesses begin to form, and the cartilages ulcerate; and even then the pain is not so severe as where the ulceration of the cartilages occurs as a primary disease, and the abscesses heal more readily, and discharge a smaller quantity of pus than in cases of this last description. At this period, the patient becomes affected with hectic fever, loses his flesh, and gradually sinks, unless the limb be removed by an operation."—(*Med. Chir. Trans. vol.* 5, *p.* 251, 252.) In the majority of cases, Mr. Brodie believes, that *the gradual progress of the enlargement, the stiffness of the joint, without pain, and the soft elastic swelling without fluctuation*, will enable the practitioner readily to distinguish this from all other diseases of the joints. However, when the diseased synovial membrane happens to be distended with a quantity of turbid serum and flakes of coagulable lymph, the complaint somewhat resembles in its feel and appearance that stage of common inflammation of the synovial membrane, where this part is less thickened, and more or less distended with coagulable lymph; but the impossibility of relieving the former case by the same means which cure the latter, and due attention to the history of the disease, will prove the difference between them.—(*Brodie, Pathol. and Surg. Obs. p.* 96.)

3. Ulceration of the articular cartilages takes place in the advanced stage of several diseases of the joints, and it also exists in many instances as a primary affection, in the early stage of which the bones, synovial membrane, and ligaments are in a natural state. If neglected, it ultimately occasions the entire destruction of the articulation. It may be the consequence of inflammation of the cartilage itself, or of the bony surface with which it is connected; but, as Mr. Brodie farther observes, in many instances there are no evident marks of the disorder being preceded by any inflammatory action in one part or the other, and the inflammation, which afterward takes place, appears rather to be the attendant upon, than the cause of, the ulcerative process. One striking peculiarity of ulceration of the articular cartilages is, that the process may take place without the formation of pus; for the disease often proceeds so far as to cause caries of the bones, and yet no purulent matter is found within the joint.—(*Pathol. and Surgical Obs. &c. p.* 117, *ed.* 2.) The investigations of the same author dispose him to believe, that a conversion of these cartilages into a soft fibrous structure is a frequent though not constant forerunner of ulceration.—(*P.* 121.) When the ulceration of the cartilage occurs in the superficial joints, it constitutes one of the diseases which have been known by the name of white-swelling. From cases which Mr. Brodie has met with, he is led to conclude, that when it takes place in the hip, it is this disease which has been variously designated by writers, the "*morbus coxarius*," the "disease of the hip," the "scrofulous hip," the "scrofulous caries of the hip-joint." At least, says Mr. Brodie, it is to this disease that these names have been principally applied, though probably other morbid affections have been occasionally confounded with it.—(*Med. Chir. Trans. vol.* 4, *p.* 236.) The ulceration of the articular cartilages takes place, as a primary disease, chiefly in children, or adults under the middle age. "Of sixty-eight persons af

fected with this disease, fifty six (according to Mr. Brodie) were under thirty years of age: the youngest was an infant of about twelve months; the oldest was a woman of sixty. As the knee is more frequently affected by inflammation of the synovial membrane, so is the hip more liable than other joints to the ulceration of the cartilaginous surfaces. In general the disease is confined to a single joint: but it is not very unusual to find two or three joints affected in the same individual, either at the same time, or in succession. Sometimes the patient traces the beginning of his symptoms to a local injury, or to his having been exposed to cold; but, for the most part, no cause can be assigned for the complaint."—(See *Med. Chir. Trans. vol.* 6, *p.* 319.)

The symptoms of the disease of the hip-joint will be described in the ensuing section, and we shall here confine our remarks to the symptoms characterizing ulceration of the cartilages of the knee, as pointed out by Mr. Brodie. They differ from those of inflammation of the synovial membrane, by the pain being slight in the beginning, and gradually becoming very intense, which is the reverse of what happens in the latter affection. The pain in the commencement is also unattended with any evident swelling, which never comes on in less than four or five weeks, and often not till after several months. It is not to be inferred, however, that every slight pain of the joint, unaccompanied with swelling, must of course arise from ulceration of the cartilages. But, says Mr. Brodie, when the pain continues to increase, and at last is very severe; when it is aggravated by the motion of the bones on each other, and when, after a time, a slight tumefaction of the joint takes place, we may conclude that the disease consists in such ulceration. The swelling arises from a slight inflammation of the cellular membrane on the outside of the joint; it has the form of the articulating ends of the bones; and for the most part it appears greater than it really is, in consequence of the muscles being wasted. No fluctuation is perceptible, as where the synovial membrane is inflamed; nor is there the peculiar elasticity which exists where the synovial membrane has undergone a morbid alteration of its structure.

Mr. Brodie has explained, however, that in some cases the swelling has a different shape, and communicates the feel of a fluctuation. This happens when inflammation of the synovial membrane, attended with a collection of the synovia of the joint, or abscesses in the surrounding soft parts, or in the articulation itself, occur as secondary diseases. When there has been considerable destruction of the soft parts from abscesses and ulceration, the head of the tibia may become dislocated and drawn towards the ham.—(See *Med. Chir. Trans. vol.* 6, *p.* 326, *&c.*) In the 9th vol. of this work, Mr. Mayo has described an acute form of ulceration of the cartilages, as displayed in three cases affecting the knee, elbow, and ankle. They were all attended with severe pain in the beginning: two ended in anchylosis, after antiphlogistic treatment for two months: and the third patient, a boy, died, during the existence of this disease, of an injury of the head. The bones of the ankle-joint were found almost stripped of cartilage; what remained of this texture was thinned, and that unequally; but it seemed in other respects unchanged, and adhered firmly to the bone.

4. I shall pass over ulceration of the synovial membrane, which Mr. Brodie considers in a separate section, and now proceed to the scrofulous white swelling. In the scrofulous disease of the joints, the bones are primarily affected, in consequence of which ulceration takes place in the cartilages covering their articular extremities. The cartilages being ulcerated, the subsequent progress of the disease (says Mr. Brodie) is the same as where this ulceration takes place in the first instance.—(*Medico-Chir. Trans. vol.* 4, *p.* 266.)

By Mr. Lloyd, scrofulous white swellings are divided into three stages; the first being that in which the affection is confined to the bone; the second, that in which the external parts become thickened and swelled; and the third being what he names the suppurative stage, attended with ulceration of the cartilages, inflammation of the synovial membrane, and abscesses.—(*On Scrofula, p.* 121.) It was formerly a common notion, that in white swellings the heads of the bones were always enlarged. Mr. Russell, I believe, is the first writer who expressed an opposite sentiment, and he distinctly declares. *that he had never heard nor known of an instance, in which the tibia was enlarged from an attack of white swelling.*—(*P.* 37.) The inaccuracy of the opinion was afterward pointed out by Mr. Lawrence, to the late Mr. Crowther, and the subject was mentioned in the earliest edition of the "First Lines of the Practice of Surgery."

Deceived by the feel of many diseased joints, and influenced by general opinion, I once supposed that there was generally a regular expansion of the heads of scrofulous bones. But, excepting an occasional enlargement, which arises from spiculæ of bony matter, deposited on the outside of the tibia, ulna, &c., and which alteration cannot be called an expansion of those bones; for a long time, I never met with the head of a bone enlarged, in consequence of the disease known by the name of white swelling. I was formerly much in the habit of inspecting the state of the numerous diseased joints which were every year amputated at St. Bartholomew's Hospital, and though I was long attentive to this point, my searches after a really enlarged scrofulous bone always proved in vain. Nor was there at that period any specimen of an expanded head of a scrofulous bone in Mr. Abernethy's museum. Within the last few years, however, a specimen of an enlargement of the upper head of the ulna has been found, and it was some time ago shown to me by Mr. Stanley. Mr. Langstaff is said to have in his possession a knee-joint, in which the femur and tibia are much expanded, "the external lamina of the bones not being thicker than when the bones are of their natural size, and the *cancelli healthy, though of rather greater solidity than natural.*"—(*Lloyd on Scrofula, p.* 148.) However, this last form of disease evidently does not resemble the common scrofulous affection of the heads of the bones. I may add, that Mr. Wilson, whose dissections were very numerous, concurs with the best modern writers concerning the rarity of an actual expansion of the substance of the heads of the bones.—(*On the Skeleton, &c., p.* 336.) I have also heard of a few other instances, in which the heads of the bones were actually enlarged in cases of white swelling. However, I believe the occurrence is far from being usual, and doubts may yet be entertained whether such enlargement is combined with the following alteration of structure. The change which the head of the tibia undergoes in many cases is first a partial absorption of the phosphate of lime throughout its texture, while at first a transparent fluid, and afterward a yellow cheesy substance, are deposited in the cancelli. In a more advanced stage, and, indeed, in that stage which most frequently takes place before a joint is amputated, the head of the bone has deep excavations in consequence of caries, and its structure is now so softened, that when an instrument is pushed against the carious part, it easily penetrates deeply into the bone. Occasionally, as Mr. Lloyd has observed, all the bones of a joint are affected in this way; but frequently only one of them.—(*On Scrofula, p.* 120.)

According to a modern writer, "The morbid affection appears to have its origin in the bones, which become preternaturally vascular, and contain a less than usual quantity of earthy matter; while at first a transparent fluid, and afterward a yellow cheesy substance is deposited in their cancelli. From the diseased bone, vessels, carrying red blood, shoot into the cartilage, which afterward ulcerates in spots, the ulceration beginning on that surface which is connected to the bone. As the caries of the bones advances, pus is collected in the joint. At last the abscess bursts externally, having formed numerous and circuitous sinuses."—(*Brodie, in Med. Chir. Trans. vol.* 4, *p.* 272, *and Pathol. Obs. p.* 227.) The above-described alteration of the structure of the bones this author has never seen in the cranium, nor in the middle of the cylindrical bones; but it is asserted by another late writer, that the cheesy matter sometimes pervades the cancelli of the whole bone, and is deposited in innumerable portions of the most minute size.—(*E. A. Lloyd, on Scrofula, p.* 120.) Also, with respect to the increased vascularity of the diseased part of the bone, although Mr. Lloyd assents to the truth of this statement, as applied to the early stage of the disorder, he represents the vascularity as afterward being diminished, in proportion as the quantity of cheese-like deposite increases.—(*Op. cit. p.* 122, 123.)

A cursory examination of a diseased joint, even when it is cut open, will not suffice to show that the heads of the bones have not acquired an increase of size. In making a dissection of this kind, in the presence of a medical friend, I found that even after the joint had been opened, the swelling had every appearance of arising from an actual expansion of the bones. The gentleman with me felt the ends of the bones after the integuments had been removed, and he coincided with me that the feel which was even now communicated seemed to be caused by a swelling of the bones themselves. But on cleaning them, the enlargement was demonstrated to arise entirely from a thickening of the soft parts. So unusual, indeed, is the expansion of the heads of the bones, that the late Mr. Crowther, who paid great attention to these cases, joined Mr. Russell in believing that such a change never happened: a conclusion not entirely correct.—(See *Practical Obs. on White Swelling, &c. edit.* 2, *p.* 14, 1808.)

Mr. Russell has particularly noticed how much the soft parts frequently contribute to the swelling. He describes the appearances on dissection thus: "The great mass of the swelling appears to arise from an affection of the parts exterior to the cavity of the joint, and which, besides an enlargement in size, seem also to have undergone a material change in structure. There is a larger than natural proportion of a viscid fluid intermixed with the cellular substance; and the cellular substance itself has become thicker, softer, and of a less firm consistence, than in a state of health."—(*On the Morbid Affections of the Knee*, *p.* 30.) The manner in which the soft parts are affected is also described by Mr. Brodie: "Inflammation takes place of the cellular membrane external to the joint. Serum, and afterward coagulable lymph, are effused; and hence arises a puffy elastic swelling in the early, and an œdematous swelling in the advanced, stage of the disease.

"Scrofula attacks only those bones or portions of bones which have a spongy texture, as the extremities of the cylindrical bones, and the bones of the carpus and tarsus; and hence the joints become affected from their contiguity to the parts which are the original seat of the disease."—(See *Medico-Chir. Trans. vol.* 4, *p.* 273.)

In the cavity of the joint we sometimes find a quantity of curd-like matter, and the cartilages absorbed in various places, but more particularly round the edges of the articular surfaces.

As the name of the disease implies, the skin is not at all altered in colour. According to Mr. Lloyd, the first decided symptom of disease in the articulating extremity of a bone, is an occasional deep-seated, dull, heavy pain, unattended by swelling, and not increased by motion; and if it be the hip, knee, or ankle which is affected, the patient keeps the knee rather bent, and never fully extends it in progression.—(*On Scrofula*, *p.* 138.) In some instances the swelling yields in a certain degree to pressure; but it never pits, and is almost always sufficiently firm to make an uninformed examiner believe that the bones contribute to the tumour. It is remarked by Mr. Brodie, that while the disease is going on in the cancellous structure of the bones, before its effects have extended to the other textures, and while there is still no evident swelling, the patient experiences some degree of pain, which, however, is never very severe, and often is so slight that it is scarcely noticed. After a time, varying from a few weeks to several months, the external parts begin to swell, and serum and coagulated lymph to be effused in the cellular membrane, so as to form a puffy, elastic swelling.—(*Pathol. Obs. p.* 231.) In the majority of scrofulous white swellings, let the pain be trivial or more severe, it is particularly situated in one part of the joint; viz. either the centre of the articulation or the head of the tibia. Sometimes the pain continues without interruption; sometimes there are intermissions; and in other instances, the pain recurs at regular times, so as to have been called by some writers periodical. Almost all authors describe the patient as suffering more uneasiness in the diseased part, when he is warm, and particularly when he is in this condition in bed.

In the early stage of the disease the swelling is mostly very inconsiderable, or there is even no visible enlargement whatever, excepting perhaps after exercise. In the little depressions, naturally situated on each side of the patella, a fulness generally first shows itself, and gradually spreads all over the affected joint. According to Mr. Lloyd, however, when the soft parts on the outside of the knee-joint permanently swell, the swelling often commences on each side, just behind the condyles, so that the joint appears wider; and he says, that he has often seen the enlargement commence by the swelling of a gland, immediately above the inner condyle. He observes, however, that there is no point of the joint where the swelling may not begin.—(*Op. cit. p.* 139.)

The patient, unable to bear the weight of his body on the disordered joint, in consequence of the great increase of pain thus created, gets into the habit of only touching the ground with his toes, and the knee being generally kept a little bent in this manner, soon loses the capacity of being completely extended again. When white swellings have lasted a good while, the knee is almost always found in a permanent state of flexion. In scrofulous cases, the pain constantly precedes any appearance of swelling; but the interval between the two symptoms differs very much in different subjects.

The morbid joint, in the course of time, acquires a vast magnitude. Still the integuments retain their natural colour, and remain unaffected. The enlargement, however, always seems greater than it really is, in consequence of the emaciation of the limb both above and below the disease.

An appearance of blue distended veins, and a shining smoothness, are the only alterations to be noticed in the skin covering the enlarged joint. The shining smoothness seems attributable to the distention, which obliterates the natural furrows and wrinkles of the cutis. When the joint is thus swollen, the integuments cannot be pinched up into a fold, as they could in the state of health, and even in the beginning of the disease.

As the distemper of the articulation advances, the cartilages ulcerate, and collections of matter form around the part, and at length burst. Their progress, as Mr. Brodie has stated, is slow, and when they burst, or are opened, they discharge a thin pus, with portions of a curd-like substance floating in it. The discharge afterward becomes less copious and thicker.—(*Pathol. Obs. p.* 234.) The ulcerated openings sometimes heal up: but such abscesses are generally followed by other collections, which pursue the same course. In some cases, these abscesses form a few months after the first affection of the joint; on other occasions, several years elapse, and no suppuration of this kind makes its appearance. They sometimes communicate with the cavity of the diseased joint, or lead down to diseased bone, portions of which occasionally exfoliate. In the generality of cases, several abscesses take place in succession, some healing up, and others ending in sinuses.

As the cartilages continue to ulcerate, Mr. Brodie has observed, that the pain becomes aggravated, though not in a very great degree, and he says that it is not severe until an abscess has formed, and the parts over it are distended and inflamed.—(*Pathol. Obs. p.* 234.)

The local mischief must necessarily produce more or less constitutional disturbance. The patient's health becomes gradually impaired, he loses his appetite and natural rest and sleep; his pulse is small and frequent; an obstinate debilitating diarrhœa and profuse nocturnal sweats ensue. These complaints are, sooner or later, followed by dissolution, unless the constitution be relieved in time, either by the amendment or removal of the diseased part. In different patients, however, the course of the disease, and its effects upon the system, vary considerably, in relation to the rapidity with which they occur.

Rheumatic white swellings, or inflammations and thickenings of the synovial membrane from cold or other causes, are very distinct diseases from the scrofulous distemper of the large joints. In the first, the pain is said never to occur without being attended with swelling. Scrofulous white swellings, on the other hand, are always preceded by a pain, which is particularly confined to one point of the articulation. In rheumatic cases, the pain is more general, and diffused over the whole joint.

Mr. Lloyd thinks, that the scrofulous white swelling may be distinguished from all other diseases of the joints, by its being attended with less pain, by the

great degree of external swelling, often existing for a long time before matter forms in the cavity of the articulation, and by the swelling being but little diminished by any discharge of matter, which may take place. In its first stage, before the interior of the joint is affected, it may be distinguished from primary ulceration of the cartilages, by the pain not being much increased by motion. The grating produced by moving the joint is also commonly less in this disease than in ordinary ulceration of the cartilages.—(*Lloyd on Scrofula*, *p.* 142.) And according to Mr. Brodie, the principal criterion between scrofulous diseases of joints and the primary ulceration of cartilages, is the little degree of pain in the former cases, which is never much complained of before an abscess forms, nor particularly severe, "except in a few instances, and in the most advanced stage of the disease, when a portion of ulcerated bone has died, and having exfoliated, so as to lie loose in the cavity of the joint, irritates the parts with which it is in contact, and thus becomes a source of constant torment."—(*Brodie's Pathol. Obs. p.* 236.)

It seems probable, that cases in which the cancellous structure of the bones is found quite undiseased, and in which the mass of disease is confined to the soft parts, are not scrofulous white swellings. Few persons who have attained the age of five and twenty, *without having had the least symptom of scrofula*, ever experience after this period of life, a first attack of the white swelling of the strumous kind. The general correctness of this observation, I believe, is universally admitted, and that there are but few exceptions to it is confirmed by the statements of Volpi, of Pavia. However, Mr. Lloyd attended a man, who, at the age of between forty and fifty, died of phthisis, and had at the time a scrofulous ankle, besides several abscesses about his hip and groin. And the same gentleman met with another patient upwards of forty years old, with a similar disease.—(*On Scrofula*, *p.* 137.) But if these patients had had no marks of scrofula in their younger days, a circumstance not specified, they form deviations from what is usual, as indeed Mr. Lloyd seems to admit. My own observations lead me to concur with Mr. Brodie, that the scrofulous affections of the joints, so frequent in children, are rare after the age of thirty.—(*Pathol. Obs. p.* 209.) This observation, however, is to be received as correct, only with reference to persons who have been free from scrofula up to that period of life. I am attending at this moment (Aug. 1829), a woman who is nearly forty, and was first attacked with a scrofulous white swelling of the left knee about a year ago; but then she had had enlarged glands in the neck in her youth, and a scrofulous ulcer of long duration is still open on one of her legs. All cases in which the internal structure of the heads of the bones become softened, previously to the affection of the cartilages and soft parts, are probably scrofulous.

Mr. Russell has noticed the frequent enlargement of the lymphatic glands in the groin, in consequence of the irritation of the disease in the knee; but he justly adds, that the secondary affection never proves long troublesome.

When the bones are diseased, the head of the tibia always suffers more than the condyles of the thigh-bone.—(*Russell.*) The articular surface of the femur sometimes has not a single rough or carious point, notwithstanding that of the tibia may have suffered a great deal. The cartilaginous coverings of the heads of the bones are generally eroded first at their edges; and in the knee, the cartilage of the tibia is always more affected than that covering the condyles of the thigh-bone. Indeed, when white swellings have their origin in the bones, and the knee is the seat of the disorder, there is some ground for supposing that it is in the tibia that the morbid mischief usually first commences.

The ligaments of the knee are occasionally so weakened or destroyed, that the tibia and fibula become more or less dislocated backwards, and drawn towards the tuberosity of the ischium, by the powerful action of the flexor muscles of the leg. It is observed by Mr. Brodie, that just as ulceration of the cartilages is sometimes followed by dislocation of the hip, so we find that dislocation of the knee occasionally takes place from the same cause. Where there has been considerable distention of the soft parts, in consequence of ulceration extending to them, the head of the tibia is gradually drawn backwards by the action of the flexor muscles; and Mr. Brodie has even known this happen, previously to the formation of any abscesses.—(*Pathol. Obs. p.* 172, *ed.* 2.)

I have seen a curious species of white swelling, in which the leg could be bent to each side for a very considerable distance, both when the knee was extended and bent; a state implying a preternatural looseness, or perhaps a destruction of the ligaments of the articulation.

Scrofulous white swellings, no doubt, are under the influence of a particular kind of constitution, termed *scrofulous* or *strumous habit*, in which every cause capable of exciting inflammation, or any morbid and irritable state of a large joint, may bring on the present severe disease. On the other hand, in a man of a sound constitution, a similar irritation would only induce common healthy inflammation of the joint. In scrofulous habits, it also seems as if irritation of a joint were much more easily produced than in other constitutions; and no one can doubt that when once excited in the former class of subjects, it is much more dangerous and difficult of removal, than in other patients.

The doctrine of particular white swellings being scrofulous diseases, is supported by many weighty reasons, the opinions of the most accurate observers, and the evidence of daily experience. Wiseman (*book* 4, *chap.* 4,) calls the *spina ventosa* a species of scrofula, and tells us that infants and children are generally the subjects of this disease. The disorder is said by Severinus to be exceedingly frequent in young subjects. Petrus de Marchettis has observed both male and female subjects affected with what are called strumous diseases of the joints, as late as the age of five-and-twenty; but not afterward, unless they had suffered from scrofula before that period of life, and had not been completely cured. R. Lowerus also maintains a similar opinion. Even though a few persons have scrofulous diseases of the joints, for the first time, after the age of twenty-five, this occurrence, like the first attack of scrofula after this period, must be considered as extremely uncommon.

Another argument in favour of the doctrine which sets down particular kinds of white swellings as scrofulous, is founded on the hereditary nature of such forms of disease.

Numerous continental surgeons, particularly Petit and Brambilla, have noticed how subject the English are both to scrofula and white swellings of the joints. We every day see that young persons afflicted with the present disease, are in general manifestly scrofulous, or have once been so. Frequently enlarged lymphatic glands in the neck denote this fatal peculiarity of constitution; and very often the patients are known to have descended from parents who had strumous disorders.—(*Crowther.*) The disease is also frequently combined with swelled mesenteric glands, or tuberculated lungs.—(*Brodie's Pathol. Obs. p.* 221.) As the same author remarks, since the disease depends upon a certain morbid condition of the general system, it is not surprising that we should sometimes find it affecting several joints at the same time, or that it should show itself in different joints in succession; attacking a second joint after it has been cured in the first, or after the first has been removed by amputation.—(*P.* 230.)

Besides the general emblems of a scrofulous constitution, which will be noticed in the article *Scrofula*, we may often observe a shining, coagulated, flaky substance, like white of egg, blended with the contents of such abscesses as occur in the progress of the disease. This kind of matter is almost peculiar to scrofulous abscesses, and forms another argument in support of the foregoing observations, relative to the share which scrofula frequently has in the origin and course of many white swellings.

Mr. Brodie's experience leads him to believe, that in scrofulous cases, the chance of ultimate recovery is much less, when the disease attacks the complicated joints of the foot and hand, than when it is situated in larger articulations of a more simple structure.—(*Pathol. and Surg. Obs. p.* 235.)

Treatment of White Swellings.—In practice we meet with all these cases, both scrofulous and rheumatic, in two opposite states; sometimes the diseased

joint is affected with a degree of acute inflammation; in other instances the malady is entirely chronic.

The imprudence of patients in walking about and disturbing the diseased part, is often the occasion of a degree of acute inflammation, which is denoted by the tenderness of the joint when handled by the surgeon, and also by the integuments feeling hotter than those of the healthy knee. When such state exists, there can be no doubt that topical bleeding, fomentations, emollient poultices, or cold saturnine lotions, are means which may be eminently serviceable. The antiphlogistic regimen is now strongly indicated. Cooling purges of the saline kind should also be exhibited. Blood may be taken from the arm, and also from the diseased part, either by means of leeches or cupping. Mr. Latta gives the preference to the latter method, whenever it can be employed; and he very properly remarks, that little advantage can be expected from topical bleeding of any kind, unless the quantity of blood taken away be considerable. Ten or twelve ounces by cupping should be taken away at a time, and the operation should be repeated at proper intervals till the tenderness and heat of the skin have entirely subsided. When leeches are used, the number ought to be considerable, and Mr. Latta recommends the application of at least sixteen or twenty.—(*System of Surgery, vol. 1, chap. 6.*)

Although antiphlogistic means are judicious when acute inflammation prevails, yet such practitioners as lose weeks and months in the adoption of this treatment are highly censurable. While the skin is hot and tender, while the joint is affected with very acute and general pain, and while the patient is indisposed with the usual symptoms of inflammatory fever, great benefit may be rationally expected from the above plan. When, however, the disease is truly chronic, different plans are indicated. In ordinary cases of scrofulous disease of the joints, Mr. Brodie considers topical bleeding as generally unnecessary.—(*Pathol. and Surg. Obs. p.* 240.)

It is quite needless to expatiate on the mode of treating white swellings complicated with acute inflammation, particularly as the treatment of those cases which consist of inflammation of the synovial membrane has been already noticed, and may be said to be applicable to other forms of white swelling, when they are attended with heat and inflammation of the soft parts. The most eligible plan of arresting the morbid process in the bones, cartilages, and soft parts surrounding the articulation, and the most successful method of lessening the chronic enlargement of the joint, are the subjects at present demanding our earnest investigation.

The works of Hippocrates, Celsus, Rhazes, Hieron, Fabricius, &c. compared with modern surgical books, will soon convince us, that the practice of the ancients, in the treatment of diseased joints, does not differ much from the plan now pursued by the best modern surgeons. Mr. Crowther remarks, that the ancients used local and general blood-letting, the actual and potential cautery, with vesicating and stimulating applications to the skin. They farther maintain, that sores produced by these means should have their discharge promoted and continued for a considerable length of time.

With regard to the cases which Mr. Brodie describes as depending upon a total loss of the natural structure of the synovial membrane, which is converted into a pulpy substance, one quarter or one half of an inch in thickness, though the progress of the disease may be somewhat checked by rest and cold lotions, it is according to this gentleman incurable, and at length it ends in ulceration of the cartilages, abscesses, &c. When there is considerable pain in consequence of the cartilages beginning to ulcerate, partial relief may be derived from fomentations and poultices; but nothing will effect a cure. Hence, when the health begins to suffer, he considers amputation to be indicated.—(*Med. Chir. Trans. p.* 254.) Whether the local use of iodine applications would be beneficial in the early stage of this form of disease, is a question that deserves farther investigation, but can only be determined by careful experience

When white swellings are accompanied with ulceration of the cartilages, all motion of the joint is extremely hurtful. Indeed, as Mr. Brodie well observes, keeping the limb in a state of perfect quietude is a very important, if not the most important circumstance, to be attended to in the treatment. According to this gentleman, it is in these cases, in which ulceration of the cartilages occurs as a primary disease, that caustic issues are usually productive of singular benefit; but he deems them of little use in any other diseases of the joints. He thinks setons and blisters, kept open with savine cerate, may also be used with advantage Bleeding is indicated only when, from improper exercise, the articular surfaces are inflamed, and there is pain and fever. Mr. Brodie asserts that the warm bath relieves the symptoms in the early stage, if it does not stop the progress of the disease; but he condemns plasters of gum ammoniac, embrocations, liniments, and frictions, as either useless or hurtful.—(See *Med. Chir. Trans. vol.* 6, *p.* 332—334.)

Topical applications, consisting of strong astringents of the mineral and vegetable kingdom, are of no service in examples of ulceration of the cartilages, or of the scrofulous form of the disease, though they often suffice for the cure of some mild descriptions of white swelling, depending upon a thickening of the synovial membrane. A decoction of oak bark, containing alum, was recommended by Mr. Russell.

My own experience will not allow me to say any thing in favour of electricity, as an application for the relief of white swellings; and it must be more likely to do harm than good, whenever the indication is to lessen irritation.

"If the tumour is quite indolent (says Richerand), the application of galvanism may be proposed; it is not, however, exempt from danger, and on one occasion where I employed it, lancinating pains and swelling of the joint were brought on by it.—(*Nosogr. Chir. t.* 3, *p.* 174, *ed.* 2.)

Mr. J. Hunter had confidence in cicuta and sea-bathing as possessing power over many scrofulous diseases, and that such diseases of the joints are often materially benefited by the patient's going to the sea-side and bathing, is a fact which cannot be doubted, whatever may be the mode of explaining the benefit thus obtained. I fully believe that sea-air and sea-bathing have a beneficial influence over scrofulous diseases of the joints; but probably their effects are produced on the part through the medium of the constitution, and they should only be recommended as an auxiliary plan, to be adopted in conjunction with other still more efficacious measures.

Every one is well acquainted with the efficacy of friction in exciting the action of the absorbents. To this principle we are to impute the great benefit which arises from what is termed *dry rubbing*, in cases of white swellings. This kind of friction is performed by the naked hands of an attendant, without using at the same time any kind of liniment or other application whatsoever, excepting sometimes a little flour, or powdered starch, and the rubbing is continued several hours every day. At Oxford, many poor persons used to earn their livelihood by devoting themselves to this species of labour, for which they were paid a stipulated sum per hour. This practice, however, is chiefly advantageous in the chronic stage of white swelling, arising from inflammation of the synovial membrane.

I look upon all merely emollient applications, such as fomentations and poultices, as quite destitute of real efficacy, except when great pain or active inflammation is present, and, though they serve to amuse the patient, they ought not to be recommended. That surgeon who only strives to please his patient's fancy, without doing any real good to him in regard to his affliction, may be considered as doing harm; because the semblance of something being done too often hinders other really useful steps from being pursued. The French surgeons are particularly liberal in the praises which they bestow on warm emollient remedies, poultices, steam of hot water, fomentations, &c., and they adduce instances of white swellings being cured in this manner. But the cases to which they refer were no doubt mere inflammations, and thickening of the synovial membrane; a disease which in general readily yields to several other plans.

The only method of treatment which my own personal experience enables me to recommend for scrofulous white swellings in a chronic state, consists in keeping up a discharge from the surface of the diseased joints. The opportunities which I have had of observing the effects of blisters and caustic issues, rather incline me, however, to prefer the former to the latter.

I have seen great good derived from both; but more from blisters than the other kind of issue. There are instances in which I should employ vesicating applications; there are others in which I should prefer making an eschar with caustic. In particular individuals blisters create so much irritation, heat, fever, and suffering, that a perseverance in them would be rashness.

The blister should always be large. Many surgeons, instead of following Mr. Crowther's plan, prefer blistering first on one side of the joint and then on the other alternately, for a considerable length of time. "Blisters (says Mr. Latta) may be put upon each side of the patella, and ought to be of such a size and shape as to cover the whole of the swelling, on the inside, from the hinder part of the joint, at the edge of the hollow of the thigh, to the edge of the patella, over the whole extent of the swelling above and below. As soon as the blister is taken off from one side, it ought to be applied to the other, and thus repeated alternately until both swelling and pain be completely removed. When this is the case, the patient ought to be directed to rub the joint well with a liniment, composed of half an ounce of camphor dissolved in two ounces of oil, with the addition of half an ounce of spir. sal ammon. caust, or, as it is now called, liquor ammoniæ. This is to be used three times a day; and in this way (continues Mr. Latta) I have successfully treated many cases of white swellings."—(*Syst. of Surgery, vol.* 1, *chap.* 6.)

In the beginning, caustic issues are even more painful than blisters; but they afterward become more like indolent sores, and are more easily kept open for a length of time than blisters. Such issues are commonly made on each side of the diseased joint, and of about the size of a half-crown. The manner of making the eschars and keeping issues open, has been already explained.—(See *Issue.*)

The question has been contested among surgical writers and practitioners, whether blisters and issues produce benefit upon the principle of counter-irritation, or in consequence of the discharge which they occasion. They probably operate efficaciously in both ways; for there is no doubt that simple rubefacients possess the power of rousing the action of the absorbents, and they may also modify the vascular action in diseased parts. Yet it is obvious that they cannot act upon the principle of counter-irritation, and they have not been here recommended particularly for white swellings, because it seems to me, that whenever some good might be derived from their employment, much more benefit might always be obtained from blisters and issues. This sentiment is confirmed by experience, and we must, therefore, impute a great degree of efficacy to the maintenance of a purulent discharge from the vicinity of the diseased part.

Though my own observations have led me to think issues and blisters as efficient as any means hitherto devised for stopping the progress of scrofulous disease of the heads of the bones, I am far from meaning to say that such disease can generally be stopped by these or any other remedies, local or general. Mr. Brodie has seldom known any benefit derived from blisters or stimulating liniments; nor has he seen the same degree of good produced by issues in scrofulous cases, as in examples of primary ulceration of the cartilages. Cold evaporating lotions in the early stage of the complaint; perfect quietude of the joint; attention to the patient's health; and riding in a carriage in the fresh air, are the means which this gentleman particularly recommends in scrofulous diseases of the joints. During the formation of abscesses, he approves of fomentations and poultices.—(*Pathol. Obs. p.* 242.)

We have noticed the efficacy of friction in exciting the action of the absorbents, by which the thickened state of parts around the affected joint may be considerably lessened, and on this principle the utility of dry rubbing arises. We have now to notice the method of producing the same effect by pressure. In St. Bartholomew's Hospital I have seen a few cases, in which the swelling of the joints was materially diminished by encircling them with strips of adhesive plaster, applied with moderate tightness.

A somewhat similar plan, though its modus operandi is differently accounted for, appears also to have been tried in France. "J'ai dans quelques occasions (says Richerand) obtenu les plus grands avantages de l'application d'un taffetas ciré autour de l'articulation tuméfiée. On coupe un morceau de cette étoffe, assez large pour envelopper la totalité de la tumeur; on en duit les bords d'une gomme dissoute dans le vinaigre, et susceptible de la faire adhérer intimement à la peau; un l'applique ensuite de manière que tout l'accès soit interdit à l'air entre lui et les teguments. Lorsque au bout de quelques jours on lève cet appareil, on trouve la peau humide, ramollie par l'humeur de la transpiration condensée en gouttelettes à la surface intérieure du taffetas. Dans ce procédé on établit un espèce de bain de vapeur autour de l'articulation malade."—(*Nosogr. Chir. t.* 3, *p.* 175, *edit.* 2.)

My friend, the late Mr. Clement Wilson Cruttwell, of Bath, sent me an excellent case illustrative of the efficacy of treatment by pressure. He remarks, that "after cupping the part, and endeavouring to quiet the inflammation, I used blisters; but they excited such intolerable pain, and produced so great a degree of swelling and inflammation, that I was under the necessity of healing them immediately. After two months' strict confinement to bed, and the use of leeches and refrigerant washes, the inflammation having again subsided, and the pain being removed, I again ventured to apply one small blister, and again a similar attack of pain, swelling, and inflammation was produced. The joint became distended with fluid, of which it had always contained a large quantity, and the irritation of the constitution was excessive. By the liberal use of opium, I once more succeeded in quieting the disturbance, and, convinced of the hazard of using blisters in such a subject, I applied moderate pressure by means of a roller, together with a wash, containing a large proportion of spirit, in order to keep up a constant evaporation. The skin, which was before much inflamed and hard, has become natural and flaccid, the pain has ceased, the swelling has diminished, and I have every prospect of effecting a cure, with the preservation of tolerably free motion in the joint."

Mr. Cruttwell, in a subsequent letter, informed me that this case got completely well, by the treatment with pressure, and had remained so for upwards of six months, under full and free exercise.

This example clearly evinces the impropriety of using blisters in certain constitutions. In some remarks annexed to the above case, Mr. Cruttwell expresses his conviction that absolute rest, cold applications, and pressure would succeed in very many cases without local counter-irritation. Pressure, he adds, succeeds best when fluid is effused, and the disease is indolent; but he is convinced that it may be used with advantage in later stages, when abscesses have formed, and sinuses already exist; and he reminds me how very serviceable continued pressure is to the scrofulous finger-joints of children.

The good effects of pressure in scrofulous cases are confirmed by the observations of Mr. Brodie: when, says he, after several abscesses have taken place, the tendency to suppuration has ceased, and the swollen joint has become diminished, anchylosis is probably disposed to take place. At this period, pressure by means of strips of linen, spread with soap cerate or some other moderately adhesive plaster, and applied in a circular manner round the limb, will be productive of benefit.—(*Pathol. and Surg. Obs. p.* 243.)

Analogous to the plans sometimes followed by M. Richerand, Mr. Cruttwell, and Mr. Brodie, is that described by Mr. Scott. According to this gentleman, issues, perpetual blisters, and other irritating remedies may all be superseded by the following treatment. The surface of the joint is first to be cleaned with sponge and soft brown soap and water, and then the roughly dried. It is next to be rubbed with a sponge soaked in camphorated spirit of wine, until it begins to feel warm, smart a little, and assume a red appearance. It is now to be covered with a cerate, composed of equal parts of ceratum saponis and the ung. hydrarg. fortius cum camphora. This is thickly spread on large square pieces of lint, and applied to every side of the joint, and this in the knee for at least six inches above and below the point at which the condyles of the femur are opposed to the head of the tibia. The limb is next to be supported to the same extent with strips of calico, spread with the emplastrum plumbi, and applied so as to prevent motion of the joint. Then is to be laid on an additional covering of emplastrum saponis, spread on thick leather, and cut into four broad pieces; one for the front, another for the back, and the two others for the sides of the joint: lastly,

the whole is secured by means of a calico bandage, which is put on very gently, and rather for the purpose of securing the plaster, and giving greater thickness and security to the whole, than for the purpose of compressing the joint.

It is remarked by Mr. Scott, that in some cases, in which the skin is thick and indolent, sufficient irritation will scarcely be excited by the above applications, and it is necessary to rub on the part a small quantity of tartar emetic ointment, previously to the application of the cerate. In some instances, and particularly in children, it is proper to adopt a plan by which the motion of the joint may be more effectually hindered. This is done by applying on each side of the joint, externally to the plasters, a piece of pasteboard softened in warm water, and cut into the length, breadth, and form of splints, and when dry it will be found to make a firm case for the limb.—(See *Surg. Obs. on the Treatment of Chronic Inflammation, &c. p.* 133, *et seq.* 8vo. *Lond.* 1828.) The applications here described are stated not to require very frequent removal. "The time during which they may be left undisturbed (says Mr. Scott) will depend chiefly on the necessity for a repetition of the bleeding, in which we must be guided by the degree of pain; or, when there are open abscesses, by the quantity of the discharge. In some cases the dressing must be renewed every week; but in the generality of examples this may remain a fortnight, and sometimes longer. Even when there are sores or sinuses, Mr. Scott lets the applications continue on the part several days or a week, as he finds the presence of the matter do less harm than the frequent disturbance of the joint. The foregoing method, combined with remedies for the improvement of the health in general, the regulation of the digestive organs, the prevention of costiveness, &c. and with occasional topical bleeding, when the state of the inflammation requires it, seems to be employed by Mr. Scott in several forms of disease of the joints, as that commencing in the synovial membrane, that beginning in the cartilages, and that which originates in the cancellous structure of the heads of the bones. He also extends the practice to diseases of the hip, and to various examples of induration and tumours, the result of chronic inflammation and scrofula. It is to be particularly noticed, that the three principles on which it acts are, first, its mechanical operation of supporting and steadying the part; secondly, its medicinal action on the same by means of the mercury blended with the cerate; and thirdly, the mild degree of counter-irritation kept up in the skin by the applications.

When the knee is affected, the limb has a tendency to become permanently bent. It must undoubtedly be judicious to prevent this position by means of pasteboard or splints, which will also serve to prevent all motion of the diseased joint, an object of the very highest importance. Were the disease to end in anchylosis, the advantage of having the limb in a state of extension is certainly very important.

In cases which commence in the cancellous structure of the heads of the bones, it seems rational to combine with the local treatment the employment of such internal remedies as have been known to do good in other scrofulous diseases. "It is to be supposed (as Mr. Brodie observes) that the air of a crowded city must be more or less unfavourable: and that a residence on the seacoast is likely to be more beneficial than a residence in the country elsewhere. The patient should live on a nourishing but plain diet; he should be in the open air in summer as much as he can, without exercising the joint. His mode of life should, in all respects, be regular and uniform." Mr. Brodie has found more benefit derived from the long use of steel medicines than any others, suspending their use, however, and substituting the mineral acids for them, when the formation of abscesses excites febrile action. With such means, in children, he combines the occasional exhibition of mercurial purgatives.—(*Pathol. Obs. p.* 245.) In a work which Mr. Lloyd has published, it is assumed as a fact, that in scrofula there always is more or less disorder of the functions of the digestive organs, and primarily of no other important function. Hence the regulation of diet, the state of the bowels, and the hepatic secretions, is with this gentleman a principal object; and with the latter views, he employs, after Mr. Abernethy's plan, five grains of the blue pill every night, and half a pint of decoct. sars. twice a day, with opening medicines, if necessary to procure regular daily evacuations. When acidity of the stomach is present, he gives soda, and when the stomach is weak, cinchona, steel, and mineral acids.—(*On Scrofula, p.* 37, *&c.*) However, no doubt can be entertained that these means, like many others, have no specific power over scrofulous diseases, and, like sea-air and sea bathing, only answer by sometimes improving the state of the constitution. In the local treatment of scrofulous joints, Mr. Lloyd commends quietude of the limb, which is to be confined in a sling, or in splints; the occasional resistance of inflammatory action by leeches, and a diminution of temperature; poultices when abscesses form; opening such collections of matter early; and, after all irritation has ceased, issues, setons, blisters, or the antimonial ointment; or compression upon Mr. Baynton's plan.—(*P.* 152, *&c.*) With respect to opening these abscesses early, Mr. Lloyd differs from many excellent surgeons, especially Dr. Albers, who distinctly states, that it is generally best to allow them to burst themselves. On this subject, however, great diversity of opinion prevails, and Langenbeck is among the advocates for making an early opening.—(*Bibl. b.* 2, *p.* 39.) Hectic symptoms are those which we commonly have to palliate in these cases. When the appetite is impaired, and the stomach will bear bark, this medicine should be given with the aromatic confection, or the sulphate of quinine may be exhibited. Above all, opium claims high recommendation, as it tends to keep off and relieve a debilitating diarrhœa, which too frequently prevails, at the same time that it alleviates pain and procures sleep. The objection made against its exhibition, on the ground that it increases perspiration, seems exceedingly frivolous, when the above important benefits are taken into consideration.

The internal and external use of iodine is also deserving of trial.—(See *Iodine.*)

Too often, however, the terrible disease of which we are now treating baffles all human skill and judgment, and the unhappy patient's health having declined to the lowest rate, he is necessitated to submit to amputation, as the only chance of preserving life. It has been explained, in speaking of *Amputation*, that the condition of the patient's health, and not of the diseased joint, forms the principal reason for recurring to the severe operation of removing the limb. If the patient's constitution be equal to a longer struggle, no man can pronounce that every prospect of saving the limb is at an end. Many diseased joints, apparently in the most hopeless condition, frequently take a favourable turn, and after all allow the limb to be saved.

The proposal of cutting out diseased joints, has been considered in the article *Amputation.*

Disease of the Hip joint.—This complaint is very analogous in its nature to the white swelling of other articulations. Like the latter disorder, it seems probable that the disease of the hip has its varieties, some of which may be connected with scrofula, while others cannot be suspected to have any concern with it. Mr. Brodie's investigations lead him to believe, however, that the disease is of that nature in which the first change is disease and ulceration of the cartilages. The present complaint is most frequently seen in children under the age of fourteen; but no age, no sex, no rank, nor condition of life, is exempt from the possibility of being afflicted, so that though children form a large proportion of those subjects who are attacked, yet the number of adults, and even of old persons, is considerable.

The approach of the disease of the hip-joint is much more insidious than that of a white swelling. Some degree of pain always precedes the latter affection; but the only forerunner of the former is frequently a slight weakness and limping of the affected limb. These trivial symptoms are very often not sufficiently urgent to excite much notice, and when observed by superficial practitioners, are commonly neither understood, nor treated according to the dictates of surgical science. As there is, also, sometimes an uneasiness in the knee when the hip is affected, careless practitioners frequently mistake the seat of disease, and I have many times seen patients on their entrance into an hospital, having a poultice on their knee, while the wrong state of the hip was not at all suspected.

This mistake is extremely detrimental to the patient,

not on account of any bad effect resulting from the applications so employed; but because it is only in the incipient period of the complaint that a favourable prognosis can be made. In this stage of the disease, mere rest and repeated topical bleeding will do more good in the course of a fortnight, than large painful issues will afterward generally accomplish in the long space of a twelvemonth.

The symptoms of the disease of the hip-joint, when only looked for in the situation of that articulation, are not very obvious. Though in some instances the attention of the surgeon is soon called to the right situation of the disease, by the existence of a fixed pain behind the trochanter major; yet it is too often the case, that mere pain about an articulation, entirely destitute of visible enlargement and change of colour, is quite disregarded as a complaint of no importance in young subjects, and as a rheumatic or gouty affection in adults. Patients frequently complain of their most painful sensations being in the groin, and all accurate observers have remarked, that, in the hip disease, the pain is not confined to the real seat of disease, but shoots down the limb in the course of the vastus externus muscle to the knee.

The pain, says Mr. Brodie, is at first trifling, and only occasional; but it afterward becomes severe and constant. It resembles a good deal the pain of rheumatism, since it often has no certain seat. As the disease advances, the pain becomes exceedingly severe, particularly at night, when the patient is continually roused from his sleep by painful startings of the limb. Sometimes he experiences a degree of relief in a particular position of the joint, and no other. As the pain increases in intensity it becomes more fixed. In the greater number of instances it is referred both to the hip and knee, and the pain in the latter joint is generally the most severe. At other times, there is pain in the knee, and none in the hip. A boy, in St. George's hospital, complained of pain in the inside of the thigh, near the middle; and another patient referred the pain to the sole of the foot. Wherever the pain is situated, it is aggravated by the motion of the joint, and especially by whatever occasions pressure of the ulcerated cartilaginous surfaces against each other.—(*Brodie's Pathol. Obs. p.* 139.)

The early symptoms of disease in the hip-joint are only strongly delineated to such practitioners as have acquired the necessary information relative to this part of surgery from careful study and extensive experience.

When the functions of a limb are obstructed by disease, the bulk of the member generally diminishes, and the muscles become emaciated. Nearly as soon as the least degree of lameness can be perceived, the leg and thigh have actually wasted, and their circumference has diminished.

If the surgeon make pressure on the front of the joint, a little on the outside of the femoral artery, after it has descended below the os pubis, great pain will be experienced.

"Soon after the commencement of the complaint (as Mr. Brodie remarks) the hip-joint is found to be tender whenever pressure is made on it either before or behind. The absorbent glands become enlarged, and occasionally there is a slight degree of general tumefaction in the groin." The same gentleman has also adverted to the curious circumstance of there being in some cases a tenderness of the parts, to which, though not diseased themselves, the pain is referred from sympathy with the disease of the hip. This occurrence he has observed in the knee several times, and in one instance in the course of the peroneal nerve. He has also seen a slight degree of puffy swelling of the knee, in a case in which pain was referred to this joint, in consequence of disease of the hip.—(*P.* 142. 143.)

The limping of the patient is a clear proof that something about the limb is wrong; and if such limping cannot be imputed to diseased vertebræ, or some recent accident; and if, at the same time, the above-mentioned emaciation of the limb exists, there is great cause to suspect that the hip is diseased, particularly when the pain is augmented by pressing the front of the acetabulum

Diseased vertebræ, perhaps, always produce a paralytic affection of both legs at once, and they do not cause painful sensations about the knee, as the hip disease does.

The increased length of the limb, a symptom that has been noticed by all practitioners since De Haen, is a very remarkable and curious occurrence in the early stage of the present disease. This symptom is easily detected by a comparison of the condyles of the os femoris, the trochanter major, and malleoli, of the diseased limb, with those parts of the opposite member, care being taken that the patient's pelvis is evenly situated. The thing is the more striking, as the increased length of the member is frequently as much as four inches. The rationale of this fact John Hunter used to explain by the diseased side of the pelvis becoming lower than the other.—(*Crowther, p.* 266.) The same thing had also been noticed by Falconer (*On Ischias, p.* 9), long before the period when Mr. Crowther printed his second edition.

It is easy (says Mr. Brodie) to understand how the crista of one ileum becomes visibly depressed below the level of the other, when the position is remembered in which the patient places himself when he stands erect. "He supports the weight of his body upon the sound limb, the hip and knee of which are in consequence maintained in the state of extension. At the same time, the opposite limb is inclined forwards, and the foot on the side of the disease is placed on the ground considerably anterior to the other, not for the purpose of supporting the superincumbent weight, but for that of keeping the person steady, and preserving the equilibrium. Of course, this cannot be done without the pelvis on the same side being depressed. The inclination of the pelvis is necessarily attended with a lateral curvature of the spine, and hence one shoulder is higher than the other, and the whole figure in some degree distorted.—(*Pathol. Obs. p.* 146.) These effects, says Mr. Brodie, are in general all removed by the patient's lying in bed a few weeks, except when the deformity has continued a long time in a young growing subject.

In justice to the memory of the late respected Dr. Albers, of Bremen, I ought here to mention, that he appears in his work on Coxalgia to have first pointed out the deformity of the spine in this disease, and the reason of such change, the tenour of his observations upon this point agreeing with those subsequently made by Mr. Brodie.

An appearance of elongation of the limb is not exclusively confined to the early stage of the morbus coxarius: it may attend other cases. I remember in one of the wards of St. Bartholomew's Hospital, a little girl with a diseased knee, whose pelvis was considerably distorted in this manner, so that the limb of the same side appeared much elongated. Her hip-joint was quite sound. This case was pointed out to Mr. Lawrence and myself by Mr. Cother of Gloucester.

Volpi, Albers, and several other foreign writers, dwell upon the fact, that the early stage of this disease is sometimes attended with an appearance of elongation, sometimes with that of a shortening of the limb. An explanation of the circumstance is given by Mr. Brodie, as follows: "In a few cases, where the patient is in the erect position, it may be observed, that the foot which belongs to the affected limb is not inclined more forwards than the other, but the toes only are in contact with the ground, and the heel raised, at the same time that the hip and knee are a little bent. This answers to the patient the same purpose of enabling him to throw the weight of his body on the other foot; but it produces an inclination of the pelvis in the opposite direction. The crista of the ileum is higher than natural, and there is an apparent shortening, instead of elongation of the limb on the side of the disease."—(*Pathol. and Surg. Obs. p.* 147.)

The late Mr. Ford called the attention of surgeons to the alteration, with respect to the natural fulness and convexity of the nates; that part appearing flattened which is usually most prominent. The gluteus magnus becomes emaciated, and its edge no longer forms so bold a line as it naturally does at the upper and back part of the thigh in the sound state of the limb.

Although this symptom, in combination with others, is of importance to be attended to, it has been explained by Mr. Brodie, that "it is not in itself to be regarded as a certain diagnostic mark of disease in the hip; since, in its early stage, this symptom is wanting; and it is met with in other diseases, in which the

muscles in the neighbourhood of the hip are not called into action, although the joint itself is unaffected."—(See *Medico-Chir. Trans. vol.* 6, *p.* 322.)

Though there may be more pain about the knee than the hip, at some periods of the malady in its incipient state, yet the former articulation may be bent and extended without any increase of uneasiness; but the os femoris cannot be moved about without putting the patient to immense torture.

The patient soon gets into the habit of bearing the weight of his body chiefly upon the opposite limb, while the thigh of the affected side is bent a little forwards, that the ground may only be partially touched with the foot. This position is found to be the most comfortable, and every attempt to extend the limb occasions an increase of pain.

This is the first stage of the disease, or that which is unaccompanied with suppuration.

The symptoms which precede the formation of pus vary in different cases, according as there is acute or chronic inflammation present. When the diseased joint is affected with acute inflammation, as generally happens, the surrounding parts become tense and extremely painful; the skin is even reddish; and symptoms of inflammatory fever prevail. When the severity of the pain abates, a swelling occurs in the vicinity of the joint, and a pointing quickly follows. In this stage, startings and catchings during sleep are said to be among the most certain signs of the formation of matter. "The shortening of the limb," says Mr. Brodie, "which usually takes place in the advanced stage of the disease, is usually, but not always, the precursor of abscess. The formation of matter is also indicated by an aggravation of the pain; by more frequent spasms of the muscles, by greater wasting of the whole limb, and by the circumstance of the thigh becoming bent forwards, and being incapable of extension," and by the pulse becoming quick, the tongue furred, and the whole system being in a state of preternatural excitement. "The abscess usually shows itself in the form of a large tumour over the vastus externus muscle; sometimes on the inside of the thigh, near the middle; and occasionally two or three abscesses appear in different parts, and burst in succession."—(*Brodie's Pathol. Obs. p.* 152.)

We have noticed the commonly lengthened state of the limb, in the first periods of the hip disease. This condition is not of very long duration, and is sooner or later succeeded by a real shortening of the affected member. The foot may be turned inwards; but, as Mr. Brodie observes, if left to itself, it is generally turned outwards. In other cases, the limb is shortened; the thigh is bent forwards; the toes are turned inwards, and do not admit of being turned outwards (*Pathol. Obs. p.* 148); and all the symptoms of a luxation of the thigh upwards and outwards may be observed, the head of the bone, indeed, being actually drawn into the external iliac fossa, and carried between the os innominatum and glutæus minimus, which is raised up by it.—(See *Richerand, Nosogr. Chir. t.* 3, *p.* 171, 172, *ed.* 2.)

When the retraction is very considerable, it arises from nothing less than an actual dislocation of the head of the thigh-bone, in consequence of the destruction of the cartilages, ligaments, and articular cavity. This retraction sometimes comes on long before any suppuration takes place. The head of the bone may be dislocated, and the disease terminate in anchylosis, without any abscess whatever. However, if suppuration has not taken place, Mr. Brodie believes it rarely happens that the limb, after the cure, does not regain its natural degree of mobility.—(See *Med. Chir. Trans. vol.* 6, *p.* 325.)

It is worthy of particular notice, that the head of the bone is always luxated upwards and outwards; and the only exception to this observation, upon record, is a case related by Cocchi, in which a spontaneous dislocation of the thigh-bone, as it is termed, happened upwards, forwards, and a little inwards.—(See *Léveillé, Nouvelle Doctrine Chir. t.* 3, *p.* 595.) On a également vu la tête du fémur luxée en dedans et en bas, et placée sur le trou obturateur, mais cette mode de déplacement consécutif, dans lequel le membre est allongé, est infiniment rare.—(*Richerand, Nosogr. Chir. t.* 3, *p.* 172.)

The hip disease generally induces hectic symptoms, after it has existed a certain time. In some subjects they soon come on; in others, the health remains unaffected a very considerable time.

"The health of the patient (says Mr. Brodie) usually suffers, even before abscesses have formed, from the want of exercise, pain, and particularly from the continued disturbance of his natural rest. I recollect no instance of an adult, in whom abscesses had formed, who did not ultimately sink exhausted by the hectic symptoms which these induced. Children may recover in this ultimate stage of the disease; but seldom without a complete anchylosis of the joint."—(*Med. Chir. Trans. vol.* 6, *loco cit.*)

When abscesses of the above description burst, they continue in general to emit an unhealthy thin kind of matter for a long time afterward; and portions of bone exfoliate from time to time.

With respect to the morbid anatomy of the disease in its incipient state, until lately little was known. A few years ago two dissections related by Mr. Ford, were, perhaps, the only ones throwing light upon this point. In one, there was a tea-spoonful of matter in the cavity of the hip-joint. The head of the thigh-bone was somewhat inflamed, the capsular ligament a little thickened, and the ligamentum teres united in its natural way to the acetabulum. The cartilage lining the cotyloid cavity was eroded in one place, with a small aperture, through which a probe might be passed, underneath the cartilage, into the internal surface of the os pubis on one side, and on the other into the os ischii; the opposite or external part of the os innominatum showing more appearance of disease than the cotyloid cavity. In the other instance, the disease was more advanced. These examples are important, inasmuch as they prove, that what is commonly called the disease of the hip-joint, primarily affects the cartilages, ligaments, and bones, and not the surrounding soft parts, as De Haen and some others would lead one to believe.

As the disorder advances, the portions of the os ischium, os ileum, and os pubis, composing the acetabulum, together with the investing cartilage, and synovial gland, are destroyed. The cartilage covering the head of the os femoris, the ligamentum teres, and capsule of the joint, suffer the same fate, and caries frequently affects not only the adjacent parts of the ossa innominata, but also the head and neck of the thigh-bone. The bones of the pelvis, however, are always more diseased than the thigh-bone, a fact which displays the absurdity of ever thinking of amputation in these cases. Mr. Ford observes, "In every case of disease of the hip joint which has terminated fatally, I have remarked, that the os innominatum has been affected by the caries in a more extensive degree than the thigh-bone itself."—(*Obs. on the Disease of the Hip-Joint, p.* 107.)

Sometimes, however, the head and neck of the thigh-bone are annihilated, as well as the acetabulum.

Mr. Brodie has had opportunities of dissecting some diseased hip-joints both in the incipient and advanced stage of the complaint. From his observations, it appears, 1st. That the disease commences with ulceration of the cartilages, generally that of the acetabulum first, and that of the femur afterward. 2. That the ulceration extends to the bones, which become carious; the head of the femur diminishing in size, and the acetabulum becoming deeper and wider. 3. That an abscess forms in the joint, which after some time makes its way by ulceration, through the synovial membrane and capsular ligament, into the thigh and nates, or even through the bottom of the acetabulum into the pelvis. Sir A. Cooper showed Mr. Brodie two specimens, in which the abscess had burst into the rectum. Sometimes the matter makes its way through the acetabulum into the pelvis. Some years ago, there was, in the London Hospital, a case, in which both hips were affected, and the abscesses communicated with the cavity of the pelvis through the acetabula.—(See *Scott on Chronic Inflammation, &c. p.* 106.) 4. In consequence of the abscess, the synovial membrane and capsular ligament become inflamed and thickened. The muscles are altered in structure; sinuses are formed in various parts, and, at last, all the soft parts are blended together in one confused mass, resembling the parietes of an ordinary abscess.—(*Medico-Chir. Trans. vol.* 4, *p.* 246, 247.)

Such are the beginning and progress of the ordinary disease of the hip-joint; but it is admitted by Mr.

Brodie, that there are other scrofulous cases in which the mischief begins in the cancellous structure of the bones, and also other instances, which consist in chronic inflammation and abscesses of the soft parts in the neighbourhood of the hip.—(*Op. cit. vol.* 6, *p.* 326.)

External violence, lying down on the damp ground in summer time, and all kinds of exposure to damp and cold, are the causes to which the disease has sometimes been referred. In almost all the cases which I have attended, the patients were decidedly scrofulous.

Treatment of the Disease of the Hip-joint.—The writings of Hippocrates, Celsus, Cælius Aurelianus, &c. prove that the ancients treated the present disease much in the same way as it is treated by the moderns. Forming an eschar, and keeping the sore open, topical bleeding, cupping, fomenting the part, &c. were all proceedings adopted in the earliest periods of surgery. Drs. Charlton, Oliver, and Falconer have spoken of Bath water as a most efficacious application to diseased hip-joints, previously to the suppurative stage. However, had not their accounts been exaggerated, all patients of this kind would long ago have flocked to Bath, and the surgeons in other places would never have had farther occasion to adopt a more painful mode of treatment. The plan pursued at Bath is to put the patient in a warm bath two or three times a week for fifteen or twenty-five minutes.

In the first stage of coxalgia, the late Dr. Albers, however, had a high opinion of warm bathing, fomentations with decoctions of herbs, and of bathing in mineral waters and the sea. But though he commenced the treatment with the frequent use of the warm bath, and continued the plan a long while, it is to be remarked, that he also combined with it an issue. After the patient had been in the bath a period not exceeding half an hour, he was taken out, and his whole body well rubbed with flannel. It appears to me that one objection to this practice must be the considerable disturbance occasioned by moving the patient in this manner every morning; for if it be true that most of these diseases commence in the cartilages of the joint, all motion of the limb must be particularly injurious.

In the early period of the disease, entire rest, the application of fomentations, and the employment of topical bleeding, particularly cupping, are highly proper. Such practice, also, is invariably judicious, whenever the case is attended with symptoms of acute inflammation. When fomentations are not applied, the lotio plumbi acetatis may be used.

This method of treatment ought never to be employed unless manifest signs of active inflammation be present. When no such state exists, this plan can only be regarded as preventing the adoption of a more efficacious one, and therefore censurable.

"When the cartilages of the hip are ulcerated (says Mr. Brodie), the patient should, in the first instance, be confined to a couch, if not to his bed; and if the disease is far advanced, the limb should be supported by pillows properly disposed, so as to favour the production of an anchylosis, by allowing it to vary as little as possible from one position."—(See *Med. Chir. Trans. vol.* 6, *p.* 335.)

Quibus diuturno dolore, says Hippocrates, *ischiadico vexatis coxa excidit, iis femur contabescet et claudicant, nisi urantur.* Forming an eschar or issue is the most efficacious plan of treating the disease even now known. A caustic issue seems to me more beneficial than a blister. The depression just behind and below the trochanter major is the situation in which surgeons usually make the issue, and the size of the eschar should be nearly as large as a crown piece. It is generally necessary to keep the issue open a very long time. When the thigh-bone is dislocated, and the patient survives, the case mostly ends in anchylosis.

For the cure of the disease in adults, Mr. Brodie and Dr. Albers have also expressed a preference to caustic issues; but in children, and even in grown-up persons when the complaint is recent, they agree in thinking blisters capable of affording complete relief. Mr. Brodie states, that in these cases they are more efficacious when kept open with the savine ointment, than when repeatedly applied. With respect to issues, he acknowledges, that behind the great trochanter is the most convenient place for them; but he believes that they have more effect when made on the outside of the joint, on the front edge of the tensor vaginæ femoris muscle. Instead of keeping the issue open with beans, Mr. Brodie has found it a more effectual practice to rub the sore two or three times a week, with the potassa fusa, or sulphate of copper. In particular cases, where the pain was very severe, this gentleman made a seton in the groin, over the trunk of the anterior crural nerve, which plan, he says, affords quicker relief, though in the end it is less to be depended upon for a cure than caustic issues.

In Doctor Alber's work, the great efficacy of issues and blisters in giving immediate relief to the severe pain in the knee, is illustrated by some valuable observations. He speaks also very favourably of the moxa, the employment of which, he says, is not very painful; a remark in which Langenbeck concurs.—(See *Bibl. b.* 2, *p.* 27.) Dr. Albers, in the hectical stages, recommends opium as highly useful, especially when combined with musk or camphor.

The occurrence of suppuration makes a vast difference in the prognosis. "The formation of even the smallest quantity of pus in the joint, in cases of this disease, in the young persons considerably diminishes, and in the adult almost precludes, the hope of ultimate recovery."—(*Brodie in Medico-Chir. Trans. vol.* 6, *p.* 347.) This gentleman is not much in favour of opening the abscesses early, at least before the joint has been kept for some time perfectly at rest. He has seen no ill consequences arise from the puncture of the lancet remaining open, and he has not found that in cases of carious joints, the method of evacuating the matter recommended by Mr. Abernethy (see *Lumber Abscess*), is attended with any particular advantage.

Mr. Scott treats this disease on the same principles as white swelling and other chronic inflammations; viz. after having got the joint into a quiet state by means of aperient medicines, topical bleeding, quietude, &c. he covers the skin with pledgets of the emplastrum saponis and strong camphorated mercurial ointment in equal proportions. These are next covered with strips of adhesive plaster, over which is laid some large pieces of soap plaster spread on thick leather. The whole is then supported with a bandage, and allowed to remain on the part a week or two, according to the circumstances already detailed in the section on white swelling.—(See *Scott on Chronic Inflammation*, *p.* 227, *&c.*)

Mr. J. Burns, in the second volume of his "Dissertations on Inflammation," p. 311, has recorded a remarkable instance in which this joint was affected with that intractable and fatal distemper, fungus hæmatodes. The case was at first supposed to be the disease of which we have just been treating in the preceding columns. The limb seemed to be elongated, and issues were employed without any material benefit. The upper part of the thigh swelled, while the lower wasted away. The patient lost his appetite, had a quick pulse, and passed sleepless nights. The part was rubbed with anodyne balsam, and laudanum given every night; but these means were only productive of temporary benefit. After some months, a difficulty of making water came on, which ended in a complete retention. It being found impracticable to introduce a catheter, and a large elastic tumour, supposed to be the distended bladder, being felt within the rectum, a trocar was pushed into the swelling. A good deal of bloody fluid was thus discharged. Afterward, a considerable quantity of high-coloured fetid urine continued to escape from the uretha. In about a week after this operation the patient died.

On dissection, Mr Burns found the hip-joint completely surrounded with a soft matter resembling brain enclosed in thin cells, and here and there other cavities full of thin bloody water, presented themselves. The acetabulum and head of the os femoris, were both carious. The muscles were quite pale, and almost like boiled liver, having lost their fibrous appearance. The same kind of substance was found in the pelvis, and most of the inside of the affected bones was carious. Large cells, containing bloody water, were observed in the diseased substance, and it was into one of these cavities that the trocar had entered when the attempt was made to tap the bladder.—*Gil Budæus De Curandis Articularibus Morbis*, 12mo. *Paris* 1539. *J. JUGULAR VEIN, how to bleed in. (See *Bleeding.*)

JUGULAR VEIN, INTERNAL, WOUNDED. Dr. Giraud cursorily mentions a case, in which a French surgeon at the military hospital of Toulouse, early in the year 1814, passed a ligature round the trunks of the common carotid artery and internal jugular vein. Both these vessels had been wounded by a musket-shot. On the sixth day from the application of the ligature, nothing unfavourable had occurred, but the final result of the case is not related.—(See *Journ. Générale de Med. &c. par Sedillot.*)

[JUGUM PENIS. A contrivance for preventing the inconvenience of an incessant dribbling of the urine in persons who are unable to retain this fluid in the bladder. A jugum penis, strictly speaking, is an instrument that operates by compressing some part of the urethra. A jugum of this kind, which was invented by Nuck, is described in Heister's Surgery.—(See *tab.* 26 *fig.* 8 *et* 9.) But when erections are likely to take place a jugum constructed on this principle is not applicable, and indeed in most cases it creates pain, and is not found to answer. Desault's contrivance for hindering a stillicidium urinæ, is noticed in the article *Urine, Incontinence of*; and a still better one was proposed by Le Rouge.—(*Journ. de Méd. Chir. et Pharmacie, t.* 76, *p.* 459.) When in men the infirmity is incurable, and a jugum cannot be worn: an apparatus for receiving the urine directly it escapes from the urethra, is the best resource. A description of such a contrivance may be found in Juville's *Traité de Bandages.* The instrument consists of three pieces; viz. an ivory mouth, a neck made of elastic gum, and a silver flask. It is fastened with pieces of tape to a leather belt, which goes round the waist. The ivory mouth is round, and about 18 lines in diameter. In its external edge there are several small holes, through which the tapes are passed, which fasten it to the belt. Its inner surface is slightly excavated, so that it may adapt itself precisely to the parts above the pubes. The outer surface is rather convex, and formed with a prominent border perforated in several places, to which the elastic gum neck or tube is fastened. This latter part must be four or five inches long, and wide enough to hold the penis; its convex end is made to screw on to the silver flask. At the upper part of the screw are three pegs, which cross each other in a stellated form, and serve for fixing a sponge within the neck. The silver flask is four inches wide, and of a flat shape; it lies on the inside of the thigh, or in a pocket made in the breeches. If necessary, a larger flask may be used. According to Mr. Mackenzie, of Glasgow, a bandage binding up the penis to the abdomen answers very well in stillicidium urinæ after lithotomy.—*Preface.*]

K

KERATONYXIS. The term *keratonyxis*, derived from κερας, a horn, and νυξις a puncture, is employed by the professors in Germany to denote the operation of couching performed through the cornea, or horny coat of the eye, the opaque lens being in this manner sometimes depressed, sometimes broken piecemeal, and in other instances merely turned, so as to place its anterior and posterior surface in the horizontal position. The latter method is what the German surgeons particularly imply by the phrase *reclination.*—See *Cataract.*

L

LACHRYMAL ORGANS, DISEASES OF THE. The lachrymal gland cannot be said to be a part which is frequently the seat of disease. Richerand has seen no instance of an inflammation of this gland, unless by this expression he implied cases, in which all the contents of the orbit are more or less affected.—(*Nosogr Chir. t.* 2, *p.* 32.) I believe, that the surrounding cellular substance is more frequently attacked with inflammation and suppuration, than the gland itself. According to Professor Beer (*Lehre von den Augenkr. b.* 1, *p.* 349), true idiopathic inflammations of the lachrymal gland are very rare, and he declares, that in the course of a practice of twenty-seven years, he has but seldom met with them. On this point he differs

from Schmidt, who fancied that he had often had under his care cases of this description in gouty and scrofulous subjects.—(*Ueber die Krankh. des Thränenorgans, p.* 134.) When the lachrymal gland is attacked with inflammation, its secretion, far from being augmented, as Richerand describes, is always considerably lessened, and therefore one of the earliest symptoms is an uneasy dry state of the eye, the secretion from the Meibomian glands and mucous membrane of the eyelids not being alone sufficient for keeping the eye duly moist and lubricated. This state is succeeded by a throbbing acute pain in the temple, shooting to the eyeball, forehead, upper and lower jaws, and back of the head. In the mean while, the temporal portion of the upper eyelid becomes swelled, tense, red, and exceedingly tender, the tunica conjunctiva being scarcely at all affected, and merely exhibiting a slight degree of redness and tumefaction towards the outer canthus. However, as the swelling of the gland increases, the eyeball becomes pushed more or less downwards and inwards towards the nose. But though there is little or no redness, nor any mark of inflammation, about the eye, this organ is tense, and extremely tender. The freedom of its movements towards the temple is much lessened in the beginning of the complaint, and when the tumour has acquired a very large size, is quite destroyed. The impairment of vision is always proportionate to the protrusion of the eyeball, the pupil being diminished, and the iris motionless. The second or suppurative stage Beer describes as ushered in by fiery appearances before the eye; an increased displacement of the eyeball; throbbing pain; great increase of the swelling of the upper eyelid, and of the conjunctiva, towards the temple; an annoying sensation of cold, and heaviness in the eye and orbit. Now, under febrile symptoms, rigors, &c. a yellowish point presents itself, either on the reddened portion of the conjunctiva, or on the outside of the eyelid, and a fluctuation becomes distinguishable.—(*Beer, Lehre, &c. b.* 1, *p.* 350.) Beer speaks of abscesses sometimes forming in the vicinity of the lachrymal gland, and terminating in a small sinus, which communicates with one of the principal excretory tubes, and discharges occasionally a thin limpid fluid.—(*Lehre von den Augenkr. b.* 2, *p.* 184.) The experience of this author leads him to consider these sinuses either as a consequence of an unskilfully treated abscess of the upper eyelid, or of a similar neglected affection of the cellular membrane, near the lachrymal gland; or, lastly, of the presence of a portion of the sac of a burst encysted tumour. According to Mr. Travers, the lachrymal gland often suppurates in children, and occasions an excessive swelling above the upper eyelid, depressing the tarsus, so as completely to conceal the eye. The abscess, he says, may be conveniently opened, and discharged beneath the eyelid.—(*Synopsis of the Diseases of the Eye, p.* 228.) With respect to the treatment of any local inflammation in and about the lachrymal gland, the best means of relief would be leeches, fomentations, emollient poultices, and other common antiphlogistic remedies. In the suppurative stage, Beer recommends mixing with the poultice a good deal of hemlock.

The lachrymal gland is subject to scirrhous enlargement, and, in cases of carcinoma of the eye, it is one of the parts in which a return of the disease is apt to occur. Hence, it is now generally considered right to remove it, as soon as the eyeball has been taken away. —(See *Eye.*) Sometimes, though rarely, the gland is primarily affected; and Guerin removed one in the state of scirrhus, and so much enlarged, that the eye was entirely covered by it. This operation was performed with such dexterity, that the external straight muscle was not at all injured. Mr. Travers removed a scirrhous and enlarged lachrymal gland. The vision of the eye had suffered considerably, during the growth of the tumour. The only deformity, after the operation, was a slight prolapsus of the eyelid. This gentleman recommends operations of this kind to be always done, if possible, beneath the eyelid.—(*Synopsis, &c. p.* 228.) The lachrymal gland, in the state of scirrhus, has been successfully removed by Mr. Todd (see *Dublin Hospital Reports, vol.* 3), and by Mr. O'Beirne, of Dublin.—(See also *Guthrie's Operative Surgery of the Eye, p.* 159, *&c.* and *J. Schmidt ueber die Krankheiten des Thränenorgans.*)

The caruncula lachrymalis is liable to chronic induration and enlargement, constituting the disease already spoken of in a foregoing part of this work, under the name of *Encanthis*, of which there is also a scirrhous, carcinomatous, or malignant form, quickly extending its effects to the eyeball and the adjacent thin bones of the orbit.—(*Beer, Lehre von den Augenkr. b.* 2, *p.* 188.)

From these subjects I proceed to consider the diseases of the excreting parts of the lachrymal organs; cases which, though of the most various natures, were formerly all confounded together, under the title of *fistula lachrymalis*, and it is only within the last few years, that these complaints have been subjected to the same principles and distinctions, which are conceived to be highly useful in other branches of surgery As Mr. M'Kenzie has judiciously remarked, the consequence of not distinguishing the different diseases of the excreting parts of the lachrymal organs from each other, has been an attempt to discover some single successful method of curing them all. "Now, there is no one method of treatment by which this can be accomplished; and hence it is, that the several remedies which have been proposed, being eminently successful in one or other of these diseases, but not adapted to all the rest, have at different times been held in such various degrees of estimation."—(*On Diseases of the Lachrymal Organs, p.* 10, 8*vo. Lond.* 1819.) And an intelligent critic observes, that in lachrymal diseases obstruction of the nasal duct appears to be almost the only circumstance against which the treatment recommended by the surgeons of France and England has been directed. "On sait qu'au rétrécissement ou a l'oblitération du canal nasal, produits par une cause quelconque, est due, dans presque tous les cas, la maladie qui nous occupe; sort que, restées intactes, les parois du sac présentent une tumeur lachrymale, d'où les larmes refluent continuellement sur les joues, à travers les points lachrymaux: soit qu'en partie detruites et ulcérées, ces parois présentent une fistule, qui offre aux larmes un passage contre nature, sans cesse entretenue par elles; en sorte que ces deux états, la tumeur et la fistule, sont presque toujours des degrés différens d'une même affection, et que le traitement qui convient à l'une répose sur les mêmes bases que celui indiqué dans l'autre."—(*Œuvres Chir. de Desault, t.* 2, *p.* 120.) It is evident from the writings of Pott and Ware, that even these authors considered the obstruction of the nasal duct as the foundation of all the train of varied symptoms presented by the excreting lachrymal organs. "An obstruction in the nasal duct is most frequently the primary and original cause of the complaint." "The seat of this disease is the same in almost every subject," says Mr. Pott (*Obs. on the Fistula Lachrymalis*); and Mr. Ware, in his observations on the same disease, sets out with the same assumption. Now, obstruction of the nasal duct is an occasional consequence merely of inflammation of the excreting lachrymal organs; in most of their diseases obstruction of the nasal duct has no part; and one might with as much propriety treat all the affections of the bladder and urethra by the dilatation of the latter part, as treat all the diseases of the excreting lachrymal organs by dilating the nasal duct. The false assumption in question has led to most erroneous treatment. For instance, in blennorrhœa of the sac, and in hernia of the sac, though in both these diseases the nasal duct is free, the common treatment in this country is to open the sac with a knife, and thrust down a style or some other instrument into the nose; thus destroying the organization of the parts which are affected merely with a gleety secretion in the one case, and with extreme relaxation in the other. Suppose (says the same critical writer) that some charlatan should make oath at the Mansion-house, that he had cured fifty or a hundred cases of gonorrhœa by opening the urethra in the perinæum, and passing a bougie through that tube, from behind forwards, who would approve of such an operation? Yet the laying open of the lachrymal sac, and thrusting a probe down into the nose, when the nasal duct is either perfectly free, or at the most slightly tumid from inflammation, is neither less preposterous nor less cruel.—(See *Quarterly Journ. of Foreign Medicine, vol* 1, *p.* 293.) Indeed it is somewhat surprising that errors of this kind should have prevailed so long, particularly as experience had taught Mr Pott that slight cases might be benefited by the simple employment of a vitriolic collyrium; a fact which ought to have convinced him

that the disease did not always depend upon obstruction of the nasal duct. It is curious, therefore, that he did not fully see this mistake; for that he knew of these diseases having great variety is evident from the following remark:—"As the state and circumstances of this disease are really various, and differ very essentially from each other, the general custom of calling them all by the one name of fistula lachrymalis is absurd." I believe that one great cause of deception has been the fact, that though laying open the lachrymal sac, and the introduction of instruments down the nasal duct, have been frequently practised when milder plans would have answered every purpose, yet a cure has often followed the practice, and thus confirmed the supposition of relief having been effected by the removal of the imaginary obstruction in the nasal duct. Thus the late Mr. Ramsden, of St. Bartholomew's, with whom I served my apprenticeship, always followed the common plan of passing a probe down the nasal duct, and letting the patient keep a piece of bougie or a style in the part for two or three months afterward; and I scarcely recollect an instance in which he failed to accomplish a cure, though I have no doubt that the same benefit might sometimes have been obtained without any operation at all. And a discerning practitioner should never forget that if no permanent obstruction exists in the nasal duct, a cure will generally follow on the subsidence of inflammation, and a change taking place in the action of the parts, whether a probe, style, cannula, bougie, or seton be employed or not.

Erysipelas of the Parts covering the Lachrymal Sac.—Beer considers it highly necessary that this case should be discriminated from inflammation of the sac itself, which is often but little affected, and this even when an abscess forms. Unless the true nature of the disease be comprehended, the surgeon is apt to suppose that the matter is in the sac itself, and believes that when he makes an opening he is puncturing that receptacle, whereas he is in reality merely dealing with a superficial abscess of the integuments. Nor, as Beer has observed, is the mistake free from ill consequences; for imagining that the wound is made into the sac, the surgeon pokes about with his probe so long, that a good deal of unnecessary pain and inflammation is produced. According to the same author, the case is not very frequent, and is mostly met with in scrofulous subjects, who have had for a considerable time a blennorrhœa of the lachrymal sac. The inflammation partakes of the usual characters of erysipelas, and commonly extends to the eyelids, particularly the upper one. The absorption and conveyance of the tears into the lachrymal sac are interrupted, because the inflammation constantly affects the lachrymal ducts and papillæ, the latter appearing considerably shrunk. When the inflammation spreads over the side of the face, Beer says there is usually a discharge of thin mucus from the nose; and when the affection extends more deeply, to the anterior portion of the lachrymal sac, as may easily happen when the case is neglected, or treated in its first stage with stimulating applications, a bean-shaped, circumscribed, hard, painful tumour may be felt or is even denoted by its very red appearance. The puncta lachrymalia are now completely closed, the papillæ shrivelled up, and the nostril on the affected side very dry and tender.

If in the first stage of the disorder, the lachrymal papillæ and canals have not been too violently affected, the former parts expand again, and the absorption of the tears recommences with the second stage. But at this period, according to the observations of Professor Beer, a good deal of mucus is secreted from the caruncula lachrymalis and Meibomian glands, and collects and glues the eyelids together, especially during sleep. At the same time, mucus generally accumulates in the lachrymal sac itself, and may be voided both through the puncta lachrymalia and nasal duct by gentle pressure. The mucous discharge from the nostril also acquires a thicker consistence. Should the lachrymal papillæ and ducts have suffered more severely in the first stage of the disease, the due absorption of the tears does not begin after the subsidence of the inflammation, and a dropping of them over the cheek, a *stillicidium lachrymarum*, frequently continues a long while after the termination of the other symptoms. It depends upon the atony of the lachrymal puncta and ducts, and is very troublesome in cold wet weather. And when the lachrymal sac itself has been a good deal inflamed in the first stage of the complaint, a large quantity of mucus collects within it in the second stage, and may be discharged by pressure. Sometimes the subcutaneous abscess actually communicates with the cavity of the sac; a case which Beer terms a spurious fistula of the lachrymal sac, the matter not being formed in that receptacle itself, but getting into it from the external abscess. As the skin is generally rendered very thin, these abscesses near the bridge of the nose usually burst by several openings. Beer remarks, that it is easy to learn whether the ulceration extends through the lachrymal sac; for when this has happened, the slightest pressure upon the superior part of the sac produces a discharge of pus and mucus from the external opening, and if the lachrymal canals have already recommenced their functions, the discharge will also be mixed with tears.—(See *M'Kenzie on Diseases of the Lachrymal Organs*, *p.* 22.) The quantity of matter which flows out is likewise so copious, that it is evident it could not have been all lodged between the skin and orbicularis palpebrarum muscle, but must have come partly out of the lachrymal sac. The use of a fine probe will remove any doubt which may be left.—(*Beer, Lehre von den Augenkr. b.* 1, *p.* 332—335.)

On the subject of the causes of this complaint, the preceding author delivers no remark worthy of notice. In speaking of the prognosis, he observes, that when the case is not neglected, nor wrongly treated in its first stage, and the inflammation has not extended to the lachrymal sac, the prognosis is very favourable: for, after the subsidence of the inflammation, a temporary atony of the lachrymal puncta and ducts, an imperfect conveyance of the tears into the nose, and, of course, a slight oozing of them over the cheek, most troublesome in cold wet weather, are the chief inconveniences which remain. But when the lachrymal sac participates in the inflammation, the prognosis is much less favourable; because, when suppuration takes place, ulceration is apt to form an opening in the front part of the sac, or else, during the second stage, a large quantity of mucus may collect in the sac, and if not skilfully treated, it frequently ends in a very obstinate blennorrhœa of that part. As Beer observes, this is a case which is often, though quite erroneously, named a fistula lachrymalis.—(*B.* 1, *p.* 336.)

The prognosis is also very favourable in the second stage of the complaint, as long as the suppuration is restricted to the integuments, and it is characterized by desquamation and scabbing; but the case is more serious when a large collection of matter forms, and particularly when the abscess makes its way into the lachrymal sac. In these last circumstances, an obstinate blennorrhœa from the sac often follows, notwithstanding the fistulous sore be treated in the most skilful manner, and sometimes the matter spreads so far around as to spoil, and even annihilate, the lachrymal canals, and cause an irremediable dropping of tears over the cheek during the rest of the patient's life.—(*Beer.*)

The suppuration (says Mr. M'Kenzie) may destroy the ligamentous layer of the lower eyelid, and end in the total obliteration of the cavity of the sac. But when the sac is not thus annihilated, and the lachrymal canals are destroyed, it is necessary that the cavity of the sac should be obliterated by artificial means; for otherwise a form of disease will follow, which Beer denominates *hydrops sacci lachrymalis*, and Mr. M'Kenzie, *mucocele*, as will be hereafter noticed.

"In common cases, a piece of folded linen, dipped in cold water, and applied to the parts affected, and the administration of gentle doses of sulphate of magnesia, make up the treatment. In severe cases, it will be found necessary not only to continue the cold applications, and to open the bowels, but to administer an emetic of tartrate of antimony, to purge freely, and even sometimes to take away blood from the arm."—(*M'Kenzie*, *p.* 24.)

In the second stage, a warm dry air, and a linen compress, are commended, with the exhibition of diaphoretics. In the first two of these means, I confess that I should place little or no confidence. When the formation of matter cannot be prevented, poultices are to be used. Beer particularly cautions us not to leave the abscess to burst of itself, but to open it immediately a fluctuation can be felt so as to prevent an ulcerated

opening from taking place in the anterior part of the lachrymal sac. And if the surgeon has not been consulted before such a communication has been established between the sac and subcutaneous abscess, he should avoid all unnecessary disturbance of the parts with probes and syringes, and at most only wash out the abscess once a day with Anel's syringe, filled with lukewarm water and a little of the vinous tincture of opium. Beer also recommends introducing into the superficial abscess, but not into the sac, a small quantity of lint, dipped in the tincture. If the blennorrhœa of the sac continue, it is to be treated in the way which will be explained in considering the second stage of inflammation of that part.

Inflammation of the Lachrymal Sac.—According to Beer, the symptoms of the first stage of this complaint are as follows: in the corner of the eye, precisely in the situation of the lachrymal sac, a circumscribed, very hard, tender swelling arises, of the shape of a bean, producing a lancinating pain when it is touched, and gradually acquiring considerable redness. The absorption and conveyance of the tears into the lachrymal sac, and thence into the nose, are completely interrupted; the lachrymal papillæ are shrunk; the puncta cannot be seen; and of course the tears fall over the cheek. The nostril on the affected side is at first very moist, but soon becomes perfectly dry, the mucous membrane being a good deal affected. As the inflammation also constantly spreads to the orbicular muscle and integuments in the corner of the eye, the complaint often presents an erysipelatous appearance, extending to the eyelids and down the cheek; but the circumscribed swelling caused by the inflamed sac is still not only capable of being distinctly felt, but even seen. It rarely happens, in cases of common inflammation, that on the change of the first stage into the second, the nasal duct is rendered impervious by an effusion of lymph; but such an occurrence is more frequent where the inflammation is not of a healthy description, and the patient is scrofulous. Under these circumstances, the lachrymal canals may also be permanently obliterated. In weak, irritable constitutions, towards the end of the first stage of the inflammation, a degree of symptomatic fever prevails, with severe headache, great redness and swelling of the whole inner canthus involving the caruncula lachrymalis, the semilunar fold, the conjunctiva, the edges of the eyelids, and the lachrymal puncta.

Here, as in inflammation of every mucous membrane, at the very commencement of the second stage, a copious morbid secretion takes place, and accumulates in large quantity; for, either in consequence of the thickening of the mucous membrane, the adhesion of the sides of the nasal duct together, or there being no mixture of the tears, the secretion within the sac cannot escape either into the nostril or out of the lachrymal puncta, and consequently it distends in a prodigious degree the anterior side of the sac, where it is uncovered by bone. Hence, the swelling is here very manifest, and a fluctuation may be felt in it, even before the suppurative stage has actually begun. According to Beer, whoever is induced by the fluctuation to open the lachrymal sac at this period, will certainly bring on a very hurtful suppuration of the part, exceedingly likely to render the excreting parts of the lachrymal organs completely unserviceable. At the beginning of the second stage, there is also a morbid secretion from the mucous membrane of the nostril and caruncula lachrymalis. Now, not only the swelling of the lachrymal sac increases more and more, but the redness acquires a deeper colour, the skin becomes more shining, the fluctuation still more evident, and at length, in the centre of the tumour formed by the lachrymal sac, a yellowish soft point presents itself. In this state of things, in order to prevent a true fistula, the surgeon should make an opening in the lachrymal sac, without the least delay; for, if the abscess be left to itself, the pus will at last make a passage for itself through the orbicular muscle and integuments; but it will only be a small fistulous opening, surrounded with callous hardness, and merely capable of letting some of the pus and mucus of the sac escape, so that the thicker part of the matter remains behind, and consequently, though the swelling diminishes after the formation of a spontaneous opening, it does not entirely subside. A quantity of blood is also remarked to be blended with the discharge from the sac. This last is the case which Beer denominates a *true fistula of lachrymal sac*. When the abscess bursts of itself, the fistulous opening in the sac is not always exactly opposite the aperture in the skin, and though there is commonly but one communication with the sac, it sometimes happens that several small external openings are produced more or less distant from the sac. The diagnosis is easy enough; for, on pressing upon the upper portion of that receptacle, mucus and pus blended together are immediately discharged from all the fistulous apertures. After the disease has lasted a good while, it not unfrequently happens that tears are also voided from the fistulous opening; a circumstance indicating the restored action of the lachrymal puncta and canals; but, according to Beer, such tears are never duly blended with the mucous and purulent matter. He farther remarks, that when the second period of the second stage, or the suppurative process, is over, a morbid secretion of mucus still continues in the third period of the second stage, that secretion becoming whitish, thick, opaque, and only partly resembling pus. As, in consequence of its thickness and the swelling of the mucous membrane of the nasal duct, the secretion cannot descend into the nose, it collects in the sac, and sometimes pushes off any piece of lint or plaster with which the external opening in the sac has been closed. At length, by means of judicious treatment, this third period of the second stage is also brought to a termination; the mucus is secreted again in due quantity; it becomes transparent like white of egg, and viscid; but white streaks may be for some time perceived in it. Afterward the mucus becomes thinner, and if the functions of the lachrymal puncta and ducts are not destroyed, it is thoroughly mixed with the tears. The opening in the lachrymal sac now either heals up of itself, or under skilful treatment; but in general a minute fistulous aperture still remains, from which the tears and mucus are occasionally voided, if the passage through the nasal duct be not free. However, if the small fistulous aperture should happen to heal up completely, the mucus and tears accumulate in the sac, and the patient is obliged to press them out through the puncta lachrymalia, several times a day.

When the surgeon is consulted early enough, and proper treatment is adopted, Beer sets down the prognosis in the first stage of the inflammation as very favourable. But if the practitioner be called in later, it will not be in his power completely to disperse the inflammation, and prevent the morbid secretion and accumulation of mucus in the lachrymal sac; the *blennorrhœa* of this part of Professor Beer, or the *dacryops blennoideus* of Schmidt; a state, however, which soon gives way to judicious treatment. But when the case is neglected or wrongly managed at the period when the lachrymal sac is violently inflamed, a complete or partial closure of the nasal duct, by adhesive inflammation, is apt to be the consequence. And the same effect may also be produced in the lachrymal canals, in which event the absorption of the tears is for ever impeded, and the patient must remain the rest of his life afflicted with the stillicidium lachrymarum.

With regard to the prognosis in the second stage of inflammation of the lachrymal sac, Beer considers it as very dubious, on account of the impairment of the functions of the excreting parts of the lachrymal organs; for, says he, no surgeon can exactly know what may have been the result of the first stage, in relation to the perviousness of the nasal duct and lachrymal canals, and an officious examination of the parts with a probe, for the purpose of obtaining information, would be attended with considerable mischief. However, generally speaking, the prognosis is most hopeful at the first period of the second stage, just when the morbid secretion of mucus is beginning; the suppuration may yet be moderated by right treatment, and the excreting parts of the lachrymal organs preserved. But if the suppurative stage has already come on, much will depend upon the consideration, whether the matter has been originally formed in the lachrymal sac, has lodged there a good while, and the sac is ready to burst, or whether there is actually an opening in the sac opposite that in the skin, or, lastly, whether the openings do not correspond. In the first case, the suppuration yet admits of being regulated by judicious treatment, and the lachrymal sac can be punctured; but in the other circumstances, the management of the

case is far more difficult, especially when the patient's constitution is not good. However, the surgeon should be careful not to disfigure the patient with a large scar; and the aim should be to prevent atony of the lachrymal puncta and ducts, and a consequent stillicidium lachrymarum. These are the least serious evils to be apprehended from mismanagement; for, if the case be ill-treated or neglected, in the later stage of the suppurative process, necessarily attending a fistulous state of the sac, the lachrymal organs may be rendered quite useless, or even entirely destroyed, and the nasal duct obliterated or obstructed by the effects of caries. In some few instances, indeed, the whole lachrymal sac is destroyed, or will require to be so by art, as will be presently explained. It is always a favourable circumstance, when the tears are seen to issue from the fistulous opening with the mucus and pus, as it is a proof that the absorption and conveyance of the tears into the lachrymal sac are established again, and that now the only question is about the state of the nasal duct, which point cannot be determined before the fistula is completely healed, and the third period of the second stage is entirely obviated.—(*Beer, Lehre von den Augenkr. b.* 1, *p.* 356—367.)

In the first stage, the indication is to endeavour to resolve the inflammation. "It is (as Mr. M'Kenzie observes) by combating the inflammation, that we are to cure this disease, and not by attacking merely one, or even several, of the symptoms. Dilatation, for instance, by the introduction of probes through the canals into the sac, and even into the nose, would only be subjecting the inflamed parts to a new course of irritation, and might thus produce effects which would render a complete cure difficult if not impossible." On the contrary, in the first stage, Mr. M'Kenzie joins Beer in praise of antiphlogistic measures; the application of cold lotions to the part; and, in severe cases, venesection and leeches are set down as proper, together with opening and diaphoretic medicines.—(*On Diseases of the Lachrymal Organs*, *p.* 33, 34.)

In the second stage, when resolution is no longer practicable, emollient applications are the most beneficial, and all debilitating means are to be stopped, by the farther use of which an incurable blennorrhœa of the lachrymal sac would be likely to be induced. And, as soon as the sac is so distended with mucus and matter, that the centre of the swelling begins to be soft, and a fluctuation is perceptible, the sac should be freely opened, so as to let its contents have a ready outlet. If, after this evacuation, there should be any deep-seated hardness of the lachrymal sac, Beer recommends the application of a camphorated hemlock poultice. Afterward the wound in the skin and sac is to have introduced into it a little bit of lint, dipped in the vinous tincture of opium, over which dressing a piece of diachylon plaster may be placed. When, under such treatment, the suppuration diminishes, but a preternatural secretion of mucus yet continues, Beer introduces into the wound every day a piece of lint, on which is spread a little bit of the following ointment: ℞. Butyri recentis insulsi, ʒss. Hydrargyri Nitrico Oxydi, gr. x. tutiæ, ptt. gr. vj. M. And, on changing the dressings, some of the following lotion may be dropped into the inner canthus, and injected lukewarm into the sac itself: ℞. Subacetatis Cupri, Potassæ Nitratis, Aluminis, ā ā gr. iij.—vj. Camphoræ tritæ gr. ij.—iv. Aquæ distillatæ ʒss. Solve et cola. Liquori colato, adde Vini Opii ʒj.—ʒij. Aquæ Rosæ ʒiv. M. Professor Beer makes a mass of the first three articles melted together in equal proportions, and terms it the *lapis divinus*, of which he makes the lotion, and then adds the other ingredients. When, by means of such treatment, the mucous secretion from the sac has been brought into a healthy state, and all the induration has subsided, the period has arrived for the surgeon to think of taking measures for the re-establishment of the passage through the nasal duct, if it should not already have become pervious of itself, which, when the inflammation has been of a healthy kind, and the treatment judicious, very frequently happens.—(*Beer, Lehre, &c. b.* 1, *p.* 369. 371.)

Chronic Blennorrhœa of the excreting Parts of the Lachrymal Organs.—Mr. M'Kenzie, whose essay contains a faithful account of Beer's opinions upon the present subject, describes the inflammation with which this form of disease commences, as seldom considerable, and in scrofulous patients it is said to be not unfrequently quite disregarded, no advice being taken until the lachrymal sac is much distended with mucus. By means of pressure upon the bean-shaped tumour, caused by such distention of the sac, a quantity of puriform mucus is forced out of the puncta lachrymalia, and overflows the eye; and so far are the lachrymal canals from being obstructed, that, excepting when any return of inflammation happens, they even absorb and convey the tears into the sac. Pressure, however, will rarely make the contents of the sac pass through the nasal duct, on account of the thickened state of the mucous membrane, and therefore the nostril is generally very dry. "In the course of this tedious disease, the accumulated mucus varies much both in quantity and quality. For instance, the mucus accumulates more rapidly, and is much thicker after a good meal, than at other times. The secretion of it is very plentiful, but thinner than usual, when the patient continues long in a moist cold atmosphere. In this case, the overflowing of the sac takes place so rapidly that the compression of the orbicularis palpebrarum in the action of winking is sufficient to evacuate the sac through the canals to such a degree, that the whole surface of the eyeball is suddenly overflowed, and the puriform fluid runs down upon the cheek. After the patient remains for a short time in a warm and dry atmosphere, the morbid secretion becomes sparing and ropy. We find that this chronic blennorrhœa almost completely disappears in many individuals during warm weather, upon which the yet inexperienced patient and the inexperienced surgeon are apt to express a great but premature joy, for, on the very first change to cold and wet weather, the disease most frequently returns."

During chronic blennorrhœa, the lachrymal sac is extremely liable to repeated attacks of inflammation, and sometimes a fistula, with a good deal of induration of the surrounding cellular substance, is produced. Mr. M'Kenzie represents this disease as the most frequent of all those to which the excreting parts of the lachrymal organs are liable, and as consisting in inflammation of these organs, modified by scrofula, general debility, disorder of the digestive organs, or other constitutional causes, which prolong its second stage. "Even regarded locally, the present disease is seldom a primary affection, but is most frequently excited by catarrhal inflammation of the Schneiderian membrane, or by a long-continued disorder of the Meibomian glands."—(*M'Kenzie on Diseases of the Lachrymal Organs*, *p.* 37—40.)

Scarpa's opinions on the present subject are in some degree peculiar to himself; for he considers the affection of the Meibomian glands and inside of the eyelids, the *puriform palpebral discharge*, as he terms it, as constituting the first degree of all those complaints which have usually gone under the name of fistula lachrymalis; the second degree or effect being the tumour of the lachrymal sac; and the third, the fistula or ulcerated opening in the latter part. Scarpa asserts that the chief part of the yellow viscid matter, which accumulates in the lachrymal sac, is secreted by the lining of the eyelids, and by the little glands of Meibomius; and that the altered quality of this secretion has a principal share in the cause of the disease. He states that the truth of this fact may at once be ascertained by everting the eyelids, and especially the lower one of the affected side; and by comparing them with those of the opposite eye. The former will always exhibit an unnatural redness of the internal membrane, which has a villous appearance all over the extent of the tarsus; while the edge of the lid is swollen, and numerous varicose vessels are distinguishable on it. The follicles of Meibomius are also turgid and prominent, and, when examined with a magnifying glass, not unfrequently appear to be slightly ulcerated.

"The villous structure, then, which the surface of the internal membrane of the palpebra assumes in these cases, becomes an organ secreting a larger quantity of fluid than usual, resembling viscid lymph, which, as before stated, being mixed with the sebaceous matter, copiously effused from the glands of Meibomius, constitutes the whole of the viscid fluid, with which the eyelids are imbued, and which is continually carried by the puncta lachrymalia into the sac, so as to fill, and also frequently distend it, until it forms a tumour.

"If, indeed, the lachrymal sac is emptied of this

matter, by means of compression, and the eye and internal surface of the palpebræ are carefully washed, so that none of the glutinous humour, pressed from the sac, may remain upon them, and the eyelids are everted half an hour afterward, the internal surface, especially of the lower one, will be found covered with a fresh effusion of mucus mixed with sebaceous matter, which has evidently not flowed back from the lachrymal sac to the eye, but has been generated between the eye and the palpebræ." Another argument brought forward by Scarpa, in support of his theory, is, that if the morbid secretion of the eyelids be retarded or suppressed, either accidentally or by means of astringent applications, little or none of the viscid secretion collects in the lachrymal sac, or can be forced out of the puncta lachrymalia. He has also constantly observed, that the puriform discharge may be radically cured at its commencement, and before it has induced any flaccidity of the sac, by a timely correction of the morbid secretion from the inside of the eyelids, and keeping the lachrymal passages cleansed, by means of injections of simple water through the puncta lachrymalia into the nose. As for the internal membrane of the sac itself, he argues that its structure does not qualify it for secreting a tenacious unctuous matter, like what is chiefly discharged from it, as it is entirely destitute of sebaceous glands, and can in reality only furnish a thin mucus. However, he admits, that if the sac happen to be inflamed and ulcerated, a turbid matter may issue from it with the tears; but, says he, this matter is true pus, and quite differ from the curdy unctuous fluid, which takes place in the puriform palpebral discharge.—(*On the Principal Diseases of the Eyes, transl. by Briggs, ed.* 2, *p.* 3—7.)

The foregoing opinions of Scarpa have not met with universal assent, and though there is probably much truth in them, he may have overlooked too much the possible simultaneous affection of the mucous membrane of the lachrymal sac and nasal duct. To Scarpa's hypothesis, Himly and Flajani have made the following objections: First, That they have observed the fistula lachrymalis, without the least morbid alteration of the eyelids and Meibomian glands. Secondly, That every puriform discharge of the eyelids is not succeeded by a fistula lachrymalis. Lastly, That the fistula lachrymalis is cured by means of the operation alone, without any attention being paid to the morbid state of the eyelids, when it exists. And Mr. Travers also regards Scarpa's account of the origin of the disease, independently of a permanent stricture, as hypothetical; for, if founded in fact, the distention of the lachrymal sac, and the regurgitation of the fluid on pressure, would attend every severe lippitudo, or ophthalmia with puriform discharge, which is not the case. If Scarpa's account were correct, Mr. Travers sees no reason why the fluid, once admitted, should be arrested, or regurgitate, instead of passing into the nose (see also *Nicod in Revue Méd. t.* 1, *p.* 155); and he thinks there is every reason to believe that the fluid, so discharged, is the proper secretion of the sac, and cases are frequent in which it is retained and cannot be expressed, owing to strictures both of the lachrymal and nasal ducts.—(*Synopsis of the Diseases of the Eye, p.* 360.) Some of the arguments with which Scarpa meets this reasoning are already anticipated, especially that which refers to the difference between the secretion of the sac itself and that of the sebaceous glands of the eyelids. Also in asserting that the origin of the fistula lachrymalis generally manifests itself on the eyelids, before the lachrymal passages are affected, Scarpa declares that he does not pretend thereby to exclude altogether the possibility of a case, in which the membranes of the nasal duct and lachrymal sac may not be thickened and ulcerated, independently of the disease of the eyelids. That this is the case, I think is evident from the account already delivered in the first two sections of this article, of Beer's opinions, respecting the consequences of inflammation of the integuments and other parts about the inner angle of the eye, as well as respecting the effects of acute inflammation of the lachrymal sac itself. However, Scarpa admits the fact, and the question left is, whether he is right in assigning the morbid secretion from the inside of the eyelids, as the most common cause of the swelling, ulceration, &c. of the lachrymal sac? That every puriform discharge from the eyelids is not followed by fistula lachrymalis, he allows is unquestionable; and this, he conceives, most probably happens because the lippitudo has not been entirely neglected, or because the secretion being less dense and viscid than usual, descends freely with the tears into the nose through the lachrymal canals, which are large and pervious. But in the acute stage of the purulent ophthalmia, he asserts that the reason why the discharge is not conveyed into the sac is, that the inflammation and swelling actually close the puncta lachrymalia, and change their direction, so that both the puriform matter and the tears fall over the cheek, and cannot descend into the sac.

As for the instances of cure, without any remedies being applied for the correction of the state of the eyelids, Scarpa deems the argument inconclusive, because particular vices of the constitution, under the use of appropriate internal remedies and a well-regulated diet, disappear, or are transferred to other parts, without the use of topical remedies.

For my own part, I am disposed to believe, that, whether the disease begin in the eyelids or elsewhere, generally both their lining and that of the sac and nasal duct are also more or less affected; and consequently, though Scarpa's theory may not be in every respect satisfactory, nor at all applicable to certain disorders of the excreting parts of the lachrymal organs, the practice, to which his sentiments lead, will, in the generality of cases, which Beer denominates *chronic blennorrhœa*, be highly advantageous.

According to Mr. M'Kenzie, the local treatment of chronic blennorrhœa does not differ essentially from that of inflammation of the excreting parts of the lachrymal organs. But every possible means must also be employed for improving the general health; for otherwise, all local remedies will be unavailing. In scrofulous cases, particular attention must be paid to diet and mode of living. In weakly persons, the preparations of iron will be highly beneficial; and when the disease is connected with disorder of the digestive organs, the treatment recommended by Mr. Abernethy is that to which Mr. M'Kenzie expresses a preference. The employment of Anel's syringe and probe is strongly reprobated. "I grant (says this author) that the application of certain substances to the mucous membrane affected, is one of the most powerful means which we possess of correcting its disposition to chronic blennorrhœa. But he who believes that the best manner of applying these substances is to inject them with Anel's syringe, introduced through the puncta, is lamentably mistaken. He is, in fact, closing his eyes upon what he must know of the functions of the several parts of the lachrymal organs, and is doing that very thing which is calculated to prolong and exasperate the disease. Except at the time of a smart renewal of the inflammation, the puncta and canals, during this disease, continue in the exercise of their functions. Whatever fluid, therefore, is dropped into the lacus lachrymarum, will be taken up by the puncta, conveyed through the canals, and applied to the whole internal surface of the sac. Even ointments placed within reach of the puncta, will be absorbed in the same manner. We ought then, first of all, to empty the sac by pressure, and, if possible, through the nasal duct into the nose. Having placed the patient upon his back, we drop into the lacus lachrymarum a small quantity of a weak solution of corrosive sublimate. ℞. aq. ros. ʒ iv. hydrarg. oxymuriatis gr. ss. gr. j. mucil. ʒj. vini opii ♁j. M. After remaining for a quarter of an hour in that position, he ought to rise, but without wiping away any of the collyrium which may remain. After another quarter of an hour, the eyelids are to be carefully dried, and a little of Janin's ophthalmic ointment applied with a camel-hair pencil to the caruncula lachrymalis and edges of the eyelids. All this is to be carefully repeated twice a day." Professor Schmidt recommends the following collyrium. ℞. Aq. rosæ, ʒ vj. acid nitrici, ♁j. alcoholis, ʒj. M. For the removal of the induration over the sac, gentle friction, with camphorated mercurial ointment, is recommended. And, says Mr. M'Kenzie, if the blennorrhœa depend upon chronic inflammation of the Meibomian glands, the diluted citron ointment is to be applied every evening at bedtime.—(*On Diseases of the Lachrymal Organs, p.* 43, *&c.*) In the first stage of what Scarpa terms the puriform discharge of the palpebræ, when the weeping is incipient, this author states that a cure may be effected without dividing the sac, or any other painful

operation. His practice consists in restraining the immoderate secretion from the Meibomian glands and internal membrane of the palpebræ, and in cleansing the sac lachrymales through their whole extent by means of injections of warm water, rendered more active by the addition of a little spirit of wine, and thrown into the puncta lachrymalia every morning and evening; a measure which, as already stated, is disapproved of by Messrs. M'Kenzie, Schmidt, &c. Scarpa considers Janin's ophthalmic ointment, weakened with lard or fresh butter, as the best application for correcting the morbid secretion of the eyelids. A portion, equal to the size of a barleycorn, is to be introduced upon the point of a blunt probe, every morning and evening, between the eye and eyelids, near the external angle, and the edges of the eyelids are to be smeared with it. The eye is then to be shut, and the eyelids gently rubbed, so that the ointment may be distributed upon the whole of their internal surface. A compress and bandage should be applied, and the eyelids kept closed for two hours. At the end of this time, the eye should be washed with the zinc collyrium. When there are superficial ulcerations at the edges of the eyelids, Scarpa applies to them either Janin's ointment, or the unguentum hydrarg. nitrat., and in very obstinate cases, the argentum nitratum itself. If the vessels of the conjunctiva are varicose, he drops into the eye the tinctura thebaica.—(*Scarpa, ed. 2, by Briggs, chap.* 1.)

The late Mr. Ware was earlier than Scarpa in pointing out the advantage of making applications to the inside of the eyelids, for the relief of certain forms of disease, usually classed with fistula lachrymalis.

"When an epiphora," says he, "is occasioned by an acrimonious discharge from the sebaceous glands on the edges of the eyelids, it must be evident that injections into the sac will be very insufficient to accomplish a cure, because the sac is not the seat of the disorder. The remedies that are employed must be directed, on the contrary, to the ciliary glands themselves, in order to correct the morbid secretion that is made by them; and for this purpose, I do not know any application that is likely to prove so effectual as the unguentum hydrargyri nitrati, of the new London Dispensatory, which should be used here in the same manner in which it is applied in common cases of the psorophthalmy. It will be proper to cleanse the eyelids every morning from the gum that collects on their edges during the night with some soft unctuous applications; and I usually advise to apply to them, two or three times in the course of the day, a lotion composed of three grains of white vitriol, in two ounces of rose or elder-flower water.—(*Additional Remarks on the Epiphora.*)

In a modern periodical work may be perused some interesting remarks by M. Nicod, which perfectly accord with the sentiment already expressed, that whatever may be its primary seat, the chronic inflammation is not generally limited to the inside of the eyelids, but extends throughout the membranous lining of the sac and nasal duct; and that this circumstance, in conjunction with the altered and viscid nature of the secretions, accounts for their not readily descending into the nose, but regurgitating through the puncta. M. Nicod also relates cases exemplifying that the ointment applied to the inside of the eyelids actually passes with the matter into the lachrymal sac, and thence into the nose, so as to act upon and cure the chronic inflammation of the sac and nasal duct, as well as that of the Meibomian glands and lining of the eyelids.—(See *Revue Medicale Historique, &c. t.* 1, *p.* 156. 8*vo. Paris*, 1820.) The proceedings for adoption, when the nasal duct is obstructed, will now be considered.

Obstruction of the Nasal Duct.—That a permanent closure of this canal does not so frequently attend diseases of the lachrymal organs as writers have generally imagined, must be evident from the remarks already delivered; and also that its perviousness, when interrupted partly by inflammation and thickening of its lining, and partly by the viscid curdy nature of the matter, may generally be restored, without thrusting any probes, tubes, or other instruments down the passage (measures, more likely, under these circumstances, to do harm than good), is a fact which is no longer questionable. The treatment necessary in such cases must be already intelligible from what has been said in the preceding sections, the indication being the diminution of the thickened state of the mucous membrane, by means adapted to the acute or chronic form of the inflammation, and in many cases, the correction also of the morbid state of the Meibomian glands and internal membrane of the eyelids. It is only when the treatment, conducted upon these mild principles, is found ineffectual, that the surgeon should think of examining the state of the nasal duct, and learning, by the introduction of a fine probe into the passage, whether any permanent stricture or obstruction is present. It does not appear to me that it is a matter of much importance, whether the probe be made of whalebone, as Beer recommends, or of silver; but that it should not be too thick is a thing certainly deserving greater attention. Supposing there is no direct opening through the skin into the lachrymal sac, one should be made with a lancet. However, a mere puncture will suffice, as a large incision, beginning just below the tendon of the orbicularis palpebrarum muscle, and extending in a semilunar form nearly an inch downwards and outwards, as used to be the old practice, can here answer no rational object, the surgeon merely having occasion for a small direct opening, through which he may conveniently pass a small probe for the purpose of ascertaining the state of the nasal duct. "The probe (as Mr. M'Kenzie observes) is to be introduced horizontally, till it touches the nasal side of the sac; it should then be raised into a vertical position, and its point directed downwards and a little backwards. Turning the probe upon its axis, we pass it from the sac into the duct; and as we continue to press it gently downwards, the instrument, if the sac is pervious, enters the nose. If its point meets with some obstruction, we must not immediately conclude, that there is an obliteration of the duct. We must press down the probe a little more strongly, yet without violence, turning it round between the fingers, and giving it different directions. By these means the obstacle is frequently overcome, and the probe suddenly descends. If the obstacle remains as before, and is extremely firm, still this is not sufficient ground for us to conclude that there is a real obliteration," because, as the author proceeds to point out, the difficulty may arise from a mere thickening of the mucous membrane, and swelling and induration of its cryptæ.—(*M'Kenzie on the Lachrymal Organs, p.* 78.)

When the probe has entered a good way down the nasal duct, and becomes as it were wedged, Beer leaves the instrument in this position, until the next time of dressing, taking care, however, to fix it to the forehead, so that it may not slip out again. At the same time he introduces into the lachrymal sac a tent, which he keeps in with a piece of sticking plaster (*Lehre von den Augenkr. b.* 2, *p.* 168); a measure which, I conceive, may be advantageously dispensed with. When at length the probe can be made to pass with some trouble into the nostril, Beer recommends introducing the instrument regularly every day, until the increased diameter of the passage allows it to be put in and withdrawn without the slightest difficulty. The period is now arrived, when Beer conceives that some measure should be taken for rendering the perviousness of the nasal duct complete and permanent, and thus entirely re-establishing the efficiency of the excreting parts of the lachrymal organs. But, says this author, whoever merely aims at restoring the natural diameter of the nasal duct by mechanical means, fulfils only one, and that not the most essential, indication. And in order that the duct may retain its natural diameter, and the tears and mucus descend freely into the nose, it is necessary that the morbid state of the mucous membrane be first removed, and the action of the excreting parts of the lachrymal organs rectified again; objects which cannot be performed by any mechanical means. Hence, Beer places considerable stress upon the necessity of obviating every unfavourable state of health likely to affect the mucous membrane of the lachrymal sac. For the purpose of restoring the natural diameter of the nasal duct, the experience of many years has convinced him that pieces of violin catgut, which are to be gradually increased in size, are the best. The end of the piece which is to be introduced, is to be first softened a little between the teeth, straightened and dipped in sweet oil. Then at least six inches of it are to be introduced, so that its lower end may be easily drawn out of the nostril; a business which Beer always lets the patient do himself. The upper portion of the catgut is coiled up, and kept within a little linen compress on the patient's fore-

head. Beer also places in the opening of the sac a small dossil of lint, and covers it with a bit of sticking plaster. In two hours the patient is to try to force the lower end of the catgut out of the nostril, by driving the air through the opening, while the mouth and opposite nostril are shut. As soon as the end of the catgut is secured, it is to be turned over the side of the nose, and fixed there with a piece of sticking plaster. The next day the bit of plaster over the sac is to be loosened with warm water, and, together with the dossil of lint, taken away, and one of the lotions hereafter specified injected down the passage. The upper end of the catgut on the forehead is next to be unfastened, and a fresh portion of it covered with some of the applications presently mentioned, when the patient is to draw it into the sac and duct, by gently pulling the end which hangs out of the nostril. The superfluous lower piece of catgut is now cut away, and the new piece turned up, and fixed to the side of the nose. The injection is again repeated, and the dressings applied as before. The same method is to be continued until the whole of the first piece of catgut is expended. Some water, coloured with the vinous tincture of opium, is now to be thrown down the sac, in order to see whether any part of the fluid will pass into the nose, and what progress has been made. Then a larger piece of catgut is employed exactly in the manner of the first; and when it is all exhausted the coloured injection is to be used again, in order to learn what advance has been made in the re-establishment of the natural diameter of the passage Lastly, a catgut of still larger size is to be used, after which the coloured injection will be found, when the patient inclines his head forwards, to run freely out of the nostril, and not merely drop into it as it did previously. When this is the state of things, all farther dilatation becomes unnecessary.—(*Beer, Lehre von den Augenkr. b.* 2, *p.* 169—172.)

This author then repeats his decided opinion that the mechanical treatment with catgut, bougies, cannulæ, &c., will only answer when attention is paid to rectifying the morbid state of the mucous membrane of the lachrymal sac by means of suitable applications, the use of which he thinks ought to commence with the first employment of the catgut. And he adds, that even such treatment will only succeed when the diseased state of the membrane of the sac is entirely a local complaint, and uncomplicated with any unfavourable condition of the health. In the beginning, if the probe can be introduced without any great trouble, and the lining of the duct is only trivially thickened, Beer moistens the catgut on its daily introduction into the passage with the vinous tincture of opium, and injects into the sac a lukewarm lotion containing the proportions of subacetate of copper, nitrate of potass, alum, camphor, and vinum opii, specified in one of the preceding columns. The lint, which Beer places in the orifice of the sac, is also dipped in the vinum opii. When the probe meets with more resistance, the catgut is smeared with the unguentum hydrargyri nitrati, which is to be at first weakened and afterward gradually increased in strength. The wound is also to be dressed with the same application, and some of the following lotion injected down the sac twice a day: ℞. Aq. ros. ʒ iv. hydrarg. oxymur. gr. j. ss. gr. j. mucil. pur. ʒ j. vini opii ℈ j. M. When any irregularities and indurated points are felt with the probe in the course of the nasal duct, Beer smears the catgut with an ointment containing a small quantity of red precipitate, and directs frictions with a little camphorated mercurial ointment to be employed every day round the external opening.

Beer joins the generality of writers in believing that a long perseverance in the mechanical means is necessary, in order to remove all disposition in the nasal duct to close again.—(*P.* 176.) And as the use of the probes, syringe, catgut, and dossils of lint may be supposed to have done more or less injury to the lachrymal ducts, so as to cause some impediment to the due conveyance of the tears into the lachrymal sac, Beer advises a trial to be made, whether a couple of drops of some coloured fluid, introduced into the inner canthus, while the patient is lying upon his back, will pass into the lachrymal sac; and if they will not do so, the same author thinks that an attempt should be immediately made to clear the lachrymal ducts by means of Anel's probe.—(*P.* 177.)

According to Beer, the foregoing treatment is perfectly useless whenever the lachrymal puncta and ducts are obliterated; because, even if it were practicable to restore their perviousness, it would yet be impossible to communicate to the new-formed apertures and canals the power of absorbing the tears and conveying them into the lachrymal sac. He thinks that in this state of things the practitioner need not trouble himself about the condition of the nasal duct; because, even if it were rendered duly pervious, this improvement would not continue long; as Beer's experience has fully convinced him, that when the mucous secretion of the lachrymal sac is not blended with the tears, a closure of the nasal duct sooner or later ensues, and of course an accumulation of the mucus of the sac, a disease sometimes termed, under such circumstances, *hydrops acculi lachrymalis*. And in order to prevent this complaint in the state of things just now described, Beer is an advocate for the total obliteration of the cavity of the sac with escharotics.—(*B.* 2, *p.* 181.)

Such is the practice of Beer, with the view of clearing away obstruction in the nasal duct and restoring its natural diameter. Let us now consider what methods have been suggested by others. Beginning then with the screw, invented by Fabricius ab Aquapendente, for compressing the distended lachrymal sac, I need only remark with M. Nicod, that as this plan was not directed against the cause of the disease, it is not surprising that it should have been unavailing, and ultimately banished from practice. In the year 1716, Anel invented a probe of so small a size that it was capable of passing from the upper punctum lachrymale into the lachrymal sac and nasal duct, the obstructions in which latter passage it was intended to remove. Anel also invented a syringe whose pipe was small enough to enter one of the puncta, and by that means to furnish an opportunity of injecting a liquor into the sac and duct; and with these two instruments he pretended to be able to cure the disease whenever it consisted in obstruction merely, and the discharge was not much discoloured. "The first of these, viz. the passage of a small probe through the puncta, (says Mr. Pott), has a plausible appearance, but will, upon trial, be found very unequal to the task assigned: the very small size of it, its necessary flexibility, and the very little resistance it is capable of making, are manifest deficiencies in the instrument; the quick sensation in the lining of the sac and duct, and its diseased state, are great objections on the side of the parts, supposing that it was capable of answering any valuable end, which it most certainly is not."—(*Pott.*)

It must be at once obvious, that Anel's instruments were devised with the view of avoiding a puncture in the lachrymal sac; but the principle has been strongly objected to by Beer, there being no comparison between the inconveniences of a small opening made in the sac and the injury done to the lachrymal puncta and canals, by the long and repeated introduction of instruments through them, whereby their functions are likely to be for ever ruined, of which Beer has known some sad examples.—(*Lehre, &c. b.* 2, *p.* 169.)

The next practice deserving notice is that of La forest, who used to introduce into the termination of the nasal duct in the nostril a probe, with which he cleared away the obstruction in the passage. He also introduced into the same orifice a curved tube, which was left in the part three or four months for the purpose of employing injections. The method, however, was found not only troublesome and difficult, on account of the anatomical varieties to which the termination of the nasal canal was liable, but also on account of the treatment, when practised, being subject to frequent failures.

Following up the principles of Anel, another French surgeon, Méjean, dilated the nasal duct with a seton, which was drawn up into the lachrymal sac by means of a thread first introduced from the upper punctum lachrymale. But it was soon discovered that what was gained on one side was lost on the other; the lodgement of the thread in the lachrymal duct for several months, and the irritation of its orifice in changing the seton every day, not only causing inflammation of the punctum lachrymale, but even such ulceration and cicatrices, as sometimes destroyed the functions of the parts.

J. L. Petit, sensible of the inconveniences of Méjean's practice, and disgusted with the barbarous imitation of

the ancients in cauterizing the fistula, sac, and os unguis, conceived that instead of these plans, or that of perforating the os unguis, as proposed by Woolhouse, "it would be better to endeavour to restore the natural passage by removing the obstruction in the nasal duct, which obstruction Petit regarded as the cause of the disease. His method consisted in opening the lachrymal sac with a small bistoury, introducing through the wound, sac, and nasal duct a probe, down into the nostril, and then using bougies for the dilatation of the passage. This method may be said to be the model of that which has been most extensively followed, even down to the present time. Pellier and Wathen recommended the introduction of a metallic tube down the ductus nasalis, and leaving it for a time in that situation, with a view of preventing the duct from closing again; and the use of a cannula is even now preferred by Dupuytren, the greatest surgeon of France.

The desire of avoiding any puncture of the sac has influenced many practitioners besides Anel, and given rise to various ingenious inventions. Thus, in 1780, Sir William Blizard proposed, instead of injecting water, to introduce quicksilver through a small pipe, communicating with a long tube full of this fluid. The specific gravity of the quicksilver, when the sac was distended with it, he believed would have more power than water propelled through a syringe, to remove the lachrymal obstruction.

The late Mr. Ware, after trying Sir William Blizard's plan, gave the preference to Anel's syringe, with which he generally injected warm water through the lower punctum lachrymale into the lachrymal sac, and put a finger over the superior punctum to prevent the fluid from escaping through it. With his finger he also occasionally compressed the lachrymal sac, in order to assist in propelling the water down into the nose. He sometimes used the injection thrice a day, though in general much less frequently.—(See *Ware on the Epiphora.*)

"I in general begin the treatment by injecting some warm water, through the inferior punctum lachrymale, and I repeat the operation four or five days in succession. If, in this space of time, none of the water pass through the duct into the nose, and if the watering of the eye continue as troublesome as it was before the injection was employed, I usually open the angular vein, or direct a leech to be applied near the lachrymal sac; adding here a caution, that the leech be not suffered to fix on either of the eyelids, lest it produce an extravasation of blood in the adjacent cells. About the same time that blood is taken away in the neighbourhood of the eye, I usually vary the injection, and try the effects either of a weak vitriolic or anodyne lotion. In some instances, also, when I have found it impossible, after several attempts, to inject any part of the liquid through the duct, I have introduced a golden probe, about the size of a bristle, through the superior punctum lachrymale, and, attending to the direction of the duct, have insinuated its extremity through the obstruction, and conveyed it fully into the nose; immediately after which I have found, that a liquid, injected through the inferior punctum, has passed without any difficulty; and by repeating these operations for a few successive days, I have at length established the freedom of the passage, and completed the cure. In other instances, I have recommended a strongly stimulating sternutatory to be snuffed up the nose, about an hour before the time of the patient's going to rest, which, by exciting a large discharge from the Schneiderian membrane, has sometimes also greatly contributed to open the obstruction in the nasal duct.

"Cases occur very rarely which may not be relieved by some of the means above related."—(*Ware's Additional Remarks on the Epiphora.*)

When the discharge was fetid, Mr. Ware sometimes found, that a vitriolic lotion, injected into the sac, quickly corrected the quality of the matter.

In a subsequent tract, Mr. Ware observes, that if, after "about a week or ten days, there be not some perceptible advance towards a cure, or if, from the long continuance of the obstruction, there be reason to fear that it is too firmly fixed to yield to this easy mode of treatment, I do not hesitate to propose the operation which is now to be described. The only persons with respect to whom I entertain any doubts as to the propriety of this opinion are infants. In such subjects I always think it advisable to postpone the operation, unless the symptoms be particularly urgent, until they are eight or nine years old.

"If the disease has not occasioned an aperture in the lachrymal sac, or if this aperture be not situated in a right line with the longitudinal direction of the nasal duct, a puncture should be made into the sac, at a small distance from the internal juncture of the palpebræ, and nearly in a line drawn horizontally from this juncture towards the nose, with a very narrow spear-pointed lancet. The blunt end of a silver probe, of a size rather smaller than the probes that are commonly used by surgeons, should then be introduced through the wound, and gently, but steadily, be pushed on in the direction of the nasal duct, with a force sufficient to overcome the obstruction in this canal, and until there is reason to believe that it has freely entered into the cavity of the nose. The position of the probe, when thus introduced, will be nearly perpendicular; its side will touch the upper edge of the orbit; and the space between its bulbous end in the nose and the wound in the skin will usually be found, in a full-grown person, to be about an inch and a quarter, or an inch and three-eighths. The probe is then to be withdrawn, and a silver style, of a size nearly similar to that of the probe, but rather smaller, about an inch and three-eighths in length, with a flat head like that of a nail, but placed obliquely, that it may sit close on the skin, is to be introduced through the duct, in place of the probe, and to be left constantly in it. For the first day or two after the style has been introduced, it is sometimes advisable to wash the eye with a weak saturnine lotion, in order to obviate any tendency to inflammation which may have been excited by the operation; but this in general is so slight, that I have rarely had occasion to use any application to remove it. The style should be withdrawn once every day for about a week, and afterward every second or third day. Some warm water should each time be injected through the duct into the nose, and the instrument be afterward replaced in the same manner as before. I formerly used to cover the head of the style with a piece of dyachylon plaster spread on black silk, but have of late obviated the necessity for applying any plaster by blackening the head of the style with sealing wax."

Mr. Ware did not, on first trying this method, expect any relief till the style was left off. However, he found, that the watering of the eye ceased, as soon as the style was introduced, and the sight became proportionably more useful and strong

The wound, which Mr. Ware makes in the sac, when there is no suitable ulcerated aperture, is only just large enough to admit the end of the probe or style; and this soon becomes a fistulous orifice, through which the style may be passed without the least pain. In short, in about a week or ten days, the treatment becomes so easy, that the patient, or any friend, is fully competent to do what is necessary. It merely consists in withdrawing the style two or three times a week, occasionally injecting some warm water, and then replacing the instrument as before.

Some, finding no inconvenience from the style, and being afraid to leave it off, wear it for years; many others disuse it in about a month or six weeks, and continue quite well. The ulcerations sometimes existing over the lachrymal sac commonly heal as soon as the tears can pass down into the nose; but Mr Ware mentions two instances, in which such sores did not heal until a weak solution of the hydrargyrus muriatus and bark were administered.—(See *Ware on the Fistula Lachrymalis.*)

Great as the recommendation of the foregoing practice is, as delivered by Mr. Ware, Mr. Travers is strongly disposed to doubt whether any permanent benefit was ever derived from letting the style remain in the passage. When an abscess over the sac has been opened, this gentleman, instead of the introduction of a style into the ductus nasalis, recommends simply the examination of the duct with a fine probe. "If the probe passes without resistance into the nose, the case requires no farther operative treatment, the integument recovers its healthy condition under an emollient application, the discharge gradually diminishes, and the wound heals. If, on the other hand, upon examination with the probe, introduced through the wound into the sac, resistance is offered to its passage into the nose, no more favourable opportunity will be presented, for

overcoming such resistance. This, therefore, should be accomplished, but to this the operative process should be limited, and the wound should be suffered to heal without farther disturbance." When there is what Mr. Travers terms a stricture in the nasal duct, and the passage of the probe is more firmly resisted, he admits that some means must be employed for keeping the duct pervious after it has been reopened. He never interferes with the integuments, except in the case of abscess discolouring the skin, and threatening to produce a fistula; and for the purpose of restoring the passage, he uses a set of silver probes, of about five inches long, of various sizes, flattened at one end, and slightly bulbous at the point. When there is no obstruction, these, he says, may be introduced with perfect facility from either of the puncta lachrymalia into the nostril. "If the punctum be constricted, it is readily entered and dilated by a common pin; and upon withdrawing it, by one of the smaller probes. The direction and relative situation of the lachrymal ducts, the sac, and nasal canal, point out the proper course of the instrument. It is confirmed by its advance, without the employment of force, and the sensation conveyed by the free and unencumbered motion of its point. Until the point is fairly within the sac, it is necessary to keep the eyelid gently stretched and slightly everted; the upper lid being drawn a little upwards towards the brow, the lower, as much downwards towards the zygoma. The point carried home to the sac, and touching lightly its nasal side, the lids may be left at liberty, while a half-circular motion is performed by the instrument; the surgeon neither suffering the point to recede, nor, on the other hand, allowing it to become entangled in the membrane. The probe now rests in a perpendicular direction upon the eyebrow, towards its inner angle, and, in this direction, it is to be gently depressed, until it strikes upon the floor of the nostril, where its presence is readily ascertained by a common probe passed beneath the inferior turbinated bone. The probe of smallest dimensions is of sufficient firmness to preserve its figure in its passage through the healthy duct, but it is too flexible to oppose any considerable obstruction. For the stricture of the lachrymal ducts, it is of sufficient strength. Very many cases of recent origin, and in which the stricture has no great degree of firmness (Mr. Travers says), are completely cured by three or four introductions of the probe into the nostril, at intervals of one or two days. I have seldom met with a stricture so firm as not to yield to the full-sized probe." When the resistance is not altogether removed, after this plan has been tried some days, Mr. Travers introduces a style, having a small flat head, a little sloped, through the punctum lachrymale into the nose, and leaves it in the nasal duct for twenty-four hours. If worn longer, he says that it causes ulceration of the orifice. A day or two is to elapse before the style is again introduced, which must now be passed through the other lachrymal duct. On the intervening days, tepid water should be injected with Anel's syringe. —(*Synopsis of the Diseases of the Eye*, *p.* 369, 370. 372. 374.)

Thus we see, that Mr. Travers's practice bears a considerable resemblance to that of Anel, inasmuch as the sac is never opened, except when likely to ulcerate, and nearly every thing is done with probes and injections, introduced through the lachrymal puncta and ducts. I wish that my views of the nature of these diseases, and of the parts concerned, would allow me to think the latter proceedings, in the case of stricture of the nasal duct, as commendable as another part of Mr. Travers's practice, where, in cases of slighter obstruction, he contents himself with opening the sac, clearing away the stoppage of the nasal duct with a probe, and healing up the wound, without leaving any style, cannula, or seton, in the passage. When the obstruction is very slight, such practice must be judicious. But if, in other cases, it be deemed right, for the prevention of a relapse, that the nasal duct should be either filled with some dilating instrument a certain time, or repeatedly probed, I am decidedly of opinion, with Professor Beer, M. Nicod, &c., that the object of not making a small opening in the sac is attended with no advantage at all likely to counterbalance the mischief which must be done to the lachrymal puncta and ducts, not only by the repeated introduction of probes and of syringes, but by the lodgement of the former in them for the space of twenty-four hours together. If there be an opening in the sac, its convenience in permitting the easy use of a probe is generally acknowledged; and in order to gain this advantage, and avoid the evils which are inseparable from taking too much liberty with the lachrymal puncta and ducts, surely a slight puncture in the sac, if there be no opening already, must be the most rational, simple, and successful practice.

When the perviousness of the nasal duct cannot be restored by any use of the probe, and the obstructed part has a very elastic feel, is of inconsiderable extent, and near the termination of the duct in the nostril, Beer recommends a perforation to be made with a trocar-shaped probe, the point of which is to be covered with a bit of wax, in order that it may not hurt the parts in its passage downwards. Some discharge of blood from the nose indicates that the perforation is made. The sharp-pointed probe is then to be withdrawn, a blunt one used for the purpose of dilating the passage, and, at length, the catgut, as already explained. —(*Beer*, *b.* 2, *p.* 181.)

Supposing the nasal duct to be obliterated, for a considerable part of its extent, by a firmer substance, what practice should then be followed? Ought the formation of an artificial passage to be attempted? On this point modern practitioners differ, but as the expedients adopted for this purpose cannot be judged of previously to their description, it will be better in the first place briefly to notice them. As Mr. Pott has remarked, the upper and hinder part of the lachrymal sac is firmly attached to the os unguis, a small and very thin bone just within the orbit, which bone is so situated, that if it be by any means broken through, the two cavities of the nose and orbit communicate with each other: consequently the os unguis forms the partition between the hinder part of the lachrymal sac and the upper part of the cavity of the nose; and it is by making a breach in this partition, that the formation of an artificial passage has been attempted. In Mr. Pott's time the cautery had long been disused for making an aperture in the os unguis, and various instruments were recommended for this object, such as a large strong probe, a kind of gimblet, a curved trocar, &c., each of which, says this practical writer, if dexterously and properly applied, will do the business very well: the only necessary caution is, so to apply whatever instrument is used, that it may pierce through that part of the bone which lies immediately behind the sacculus lachrymalis, and not to push it too far up into the nose, for fear of injuring the os spongiosum behind, while it breaks its way. Mr. Pott adds, that he himself has always used a curved trocar, the point of which should be turned obliquely downwards from the angle of the eye towards the inside of the nose. The accomplishment of the breach will be known by the discharge of blood from the nostril, and of air from the wound, upon blowing the nose. Care must be taken to apply the instrument to the part of the bone anterior to the perpendicular ridge which divides it.

As soon as the perforation is made, a tent of lint should be introduced, of such size as to fill the aperture, and so long as to pass through it into the cavity of the nose: this should be permitted to remain in two, three, or four days, and afterward a fresh one should be passed every day, until the clean granulating appearance of the sore makes it probable that the edges of the divided membrane are in the same state. The business now is to prevent the incarnation from closing the orifice; for which purpose, the end of the tent may be moistened with diluted vitriolic acid; or a piece of lunar caustic, so included in a quill as to leave little more than the extremity naked, may at each dressing or every other, or every third day, be introduced; by which the granulations will be repressed, and the opening maintained: and when this has been done for some little time, a piece of bougie of proper size, or a leaden cannula, may be introduced instead of the tent; and leaving off all other dressings, the sore may be suffered to contract as much as the bougie will permit; which should be of such length, that one extremity of it may lie level with the skin in the corner of the eye, and the other be within the nose.

The longer time the patient can be prevailed upon to wear the bougie, the more likely will be the continuance of the opening; and when it is withdrawn, the external orifice should be covered only by a superficial

pledget or plaster, and suffered to heal under moderate pressure.—(*Pott.*)

After the perforating instrument was withdrawn, Mr. Ware recommended a nail-headed style, about an inch long, to be introduced through the aperture, in the same way in which it is introduced through the nasal duct, in cases in which the obstruction is not so great as to prevent its passing in this direction; and it may remain here with as much safety as in this last-mentioned instance, for as long a time as its continuance may be thought necessary to establish the freedom of the communication.

Unfortunately for the scheme of making an artificial passage, nature was generally so busy, that she completely frustrated the aim of the surgeon by gradually filling up the new aperture again. Hence some practitioners were not content with drilling a hole through the os unguis, but actually removed a portion of this bone; either with the forceps proposed by Lamorier in 1729 (see *Mém. de l'Acad. des Sciences*), or with cutting instruments, among which the most celebrated is the sharp-edged kind of cannula devised by Hunter. While this was being applied, however, it was necessary to support the os unguis with something passed up the nose, and a piece of horn was found to answer very well. Instead of these methods Scarpa prefers destroying a portion of the os unguis with the actual cautery passed through a cannula; a practice long ago banished from good surgery, and most justly condemned by Richter.

I do not feel it necessary to enter very particularly into the details of these methods of forming an artificial passage between the lachrymal sac and nostril. I have never seen a case in which I should have deemed such practice advisable; and that the necessity for it must be rare may be inferred from what Mr. Travers has observed, viz. that he does not believe the perforation of the os unguis ever really required.—(*Synopsis, &c. p.* 379.) Beer's remarks are also decidedly against the practice; for he states, that in order that the new opening may not be closed with lymph, it must be made too high up to serve the purpose of a drain, through which the mucus can descend by its own gravity. He has not met with a single case, either in his own practice, or among the patients whom he has had opportunities of seeing under other practitioners, where the perforation of the os unguis had a successful result. On the contrary, in one healthy lad, the operation, which had been done by an experienced surgeon, was followed by the destruction of the nasal process of the upper maxillary bone, one of the ossa nasi, and all the bones contributing to the formation of the passage from the orbit into the nose.—(See *Lehre von den Augenkr. b.* 2, *p.* 182.) Hence, Beer thinks that the patient had better either submit to the inconvenience of being obliged to empty the distended sac by pressure several times a day, or let the cavity of the sac be obliterated by means calculated to excite the adhesive inflammation in it. But if the lachrymal puncta and ducts, as well as the nasal duct, are obliterated, Beer conceives that there is no alternative; because if the cavity of the sac be left, the case which he terms hydrops sacculi lachrymalis will ensue whenever the fistula is closed.

Of Hernia and Hydrops of the Lachrymal Sac.—The diseases described by Beer under these appellations are not discriminated in this country, although they are characterized by widely different symptoms, and require opposite methods of treatment. In the case of hernia or simple relaxation, the lachrymal sac forms a tumour which never surpasses the size of a common horse-bean, the integuments are of their natural colour, the tumour is soft and yielding to pressure, by which the contents of the sac are readily discharged through the puncta or nasal duct. Hydrops grows to the size of a pigeon's egg, is purplish from the beginning, very hard, and incapable of being emptied by the strongest pressure. Hernia is cured by compression, and the application of astringents to the relaxed parts; hydrops requires the incision of the sac. In hernia the nasal duct is natural, in hydrops, it and sometimes the puncta are obstructed.

Stillicidium Lachrymarum.—According to Beer, the valuable treatise of Schmidt is the only work in which the important practical distinction is drawn between stillicidium lachrymarum and epiphora; the immediate cause of the first complaint being some impediment to the passage of the tears from the lacus lachrymarum into the lachrymal sac, while the other affection consists in a redundant and extraordinary secretion of the tears. The curable form of stillicidium, here to be noticed, arises from relaxation of the lachrymal puncta and canals, in consequence of previous inflammation of the parts. The puncta are widely open; but, in other respects, have quite a natural appearance. When touched with Anel's probe they do not contract, as in the healthy state. The tears, which from time to time fall over the cheek, are not in considerable quantity, only trickling from the inner canthus by drops at intervals; and the nostril on the affected side is found to be rather drier than natural.

Erysipelatous inflammation of the eyelids and parts over the lachrymal sac, and the purulent kinds of ophthalmy, frequently cause this sort of stillicidium. The latter cases, indeed, the more readily produce the disorder, inasmuch as the semilunar fold of the conjunctiva is relaxed and swelled, so as to push the puncta out of their right position for the due performance of the absorption of the tears, and obstruct this function more than would be the case if the diminished action of those orifices and the lachrymal ducts were the only thing concerned.

Beer delivers an exceedingly favourable prognosis, observing, that the complaint often disappears of itself on the approach of warm dry weather, and may almost always be readily cured by means of astringents. Among other remedies specified by this author, I need only mention a solution of the sulphate of iron, to which a small quantity of camphorated spirit or tincture of opium has been added. It is to be dropped out of a pen into the inner angle frequently in the course of the day, the patient lying upon his back for some time after each application, so as to let the medicine have more effect upon the parts.—(See *Lehre von den Augenkr. b.* 2, *p.* 41—43.)

Mr. Travers mentions a constricted state of the lachrymal puncta and canals, which is curable by the introduction of a small probe.—(*Synopsis, &c. p.* 366.) All modern writers agree that the obliterated puncta and canals can never be restored.—See *Mémoires de l'Academie de Chirurgie, t.* 5, *ed.* 12*mo. in which are several essays on fistula lachrymalis: viz. one by M. Bordenave, entitled,* "*Examen des Réflexions Critiques de M. Molinelli, insérées dans les Mémoires de l'Institut de Bologne, contre le Mémoire de M. Petit, sur la Fistula Lachrymale, inséré parmi ceux de l'Acad. LAGOPHTHALMIA, or LAGOPHTHALMOS. (From λαγος, a hare; and ὀφθαλμὸς, an eye.) *The Hare's Eye. Oculus Leporinus.* A disease, in which the eye cannot be completely shut. The following complaints may arise from it: a constant weeping of the organ, in consequence of the interruption of the alternate closure and opening of the eyelids, which motions so materially contribute to the propulsion of the tears into the nose; blindness in a strong light, in consequence of the inability to moderate the rays, which enter the eye; on the same account, the sight becomes gradually very much weakened; incapacity to sleep where there is any light; irritation, pain, and redness of the eye, from its being exposed to the extraneous substances in the atmosphere.

An enlargement or protrusion of the whole eye, or a staphyloma, may obviously produce lagophthalmos. But affections of the upper eyelids are the common causes. Heister saw the complaint produced by a disease of the lower one. Now and then lagophthalmos depends on paralysis of the orbicularis muscle. A cicatrix, after a wound, ulcer, or burn, is the most frequent cause.

When lagophthalmos arises from a paralytic affection of the orbicularis palpebrarum, the eyelids may be rubbed with a liniment containing the tinctura lyttæ, or the linimentum camphoræ. Electricity and cold bathing are also considered the principal means of cure (*Chandler*), together with the exhibition of bark, the use of the shower-bath, &c.

When the affection arises from spasm of the levator palpebræ superioris, the surgeon may try electricity, a small blister on the neighbouring temple, and rubbing the eyelid and eyebrow with the tinctura opii, and prescribe antispasmodic medicines.

When lagophthalmos arises from the contraction of a cicatrix, its relief is to be attempted precisely on the same principles as are applicable to ectropium.—(See *Ectropium.*) However, when the eyelid is shortened as well as everted, nothing will remove the deformity.

The inconveniences depending on the eye being unable to shelter itself from the light, are to be obviated by means of a green shade.

Whoever is acquainted with German, and is desirous of more minute information on this subject, may find an excellent account of lagophthalmos in *Richter's Anfangsgr. der Wundarzn. b.* 2; *von dem Hasenauge.* See also *Beer's Lehre von den Augenkr. b.* 2, *p.* 239, *&c.* 8*vo. Wien*, 1817.

LARYNGOTOMY. (From λάρυγξ, the larynx; and τέμνω, to cut.) The operation of making an opening into the larynx.—(See *Bronchotomy.*)

LATERAL OPERATION. One mode of cutting for the stone.—(See *Lithotomy.*)

LENTICULAR. (From *lenticulaire*, doubly convex.) An instrument contained in every trephining case, and employed for removing the irregularities of bone from the edge of the perforation made in the cranium with the trephine. One side of its blade is convex, the other concave; and one of its edges is sharp. On the end of the blade is fixed a little shallow cup, with its concavity towards the handle of the instrument. This part serves the purposes of receiving the little pieces of bone, when detached, keeping the end of the blade from hurting the dura mater, and, when applied under the margin of the opening, enables the operator to guide the edge of the instrument all round it with steadiness and security.

LEUCOMA. (From λευκὸς, white.) Leucoma and albugo are often used synonymously, to denote a white opacity of the cornea. Both of them, as Scarpa remarks, are essentially different from the nebula of the cornea; for they are not the consequence of chronic ophthalmy, with varicose veins, and an effusion of a milky serum into the texture of the delicate continuation of the conjunctiva over the cornea, but are the result of violent acute ophthalmy. In this state, a dense coagulating lymph is extravasated from the arteries; sometimes superficially, at other times deeply into the substance of the cornea. On other occasions, the disease consists of a firm callous cicatrix on this membrane, the effect of an ulcer or wound, with loss of substance. The term *albugo* strictly belongs to the first form of the disease; *leucoma* to the last, more particularly when the opacity occupies the whole or the chief part of the cornea.

The recent albugo, remaining after the cure of severe acute ophthalmy, is of a clear milky colour; but, when of ancient date, it becomes pearl-coloured.

The recent albugo (provided the organization of the cornea be not destroyed) may generally be dispersed by the means employed for the relief of the first and second stages of acute ophthalmy; viz. general and topical blood-letting, with internal antiphlogistic medicines and topical emollients for the first; slightly irritating and corroborant applications for the second. As soon as the inflammation has subsided, the latter should be employed; for, by exciting the absorbents to remove the coagulating lymph, deposited in the cornea, they restore the transparency of this membrane.

But, though this may often be accomplished in the recent state of albugo, it is more difficult when the long duration of the disease has paralyzed the absorbents of the affected part; or when the deposition of a dense tenacious substance into the cornea has subverted its organization.—(*Scarpa.*)

The recent condition of the disease, without disorganization of the structure of the cornea; its occurrence in young subjects whose absorbents are readily excited by external stimulants, are circumstances favourable to the cure. In children, the albugo arising from severe ophthalmy after the small pox, and insulated in the centre of the cornea, very often disappears of itself in the course of a few months. Heister, Langguth, and Richter make the same observation. The event can only be imputed to the vigorous action of the lymphatics in children, and to the organization of the cornea not being destroyed. For promoting this absorption, Scarpa recommends the following collyrium: ℞. Ammon. muriatæ, ℈ij. Cupri acetati, gr. iv. Aquæ calcis, ℥ viij. Misce. The fluid is to be filtered after standing twenty-four hours. He praises also this ointment: ℞. Tutiæ præpar. ʒj. Aloes. s. p. gr. ij. Hydrargyri submur. gr. ij. Adipis suillæ, ℥ ss. Misce; and the unguentum ophthalmicum of Janin. He mentions the gall of the ox, sheep, pike, and barbel, applied to the cornea two or three times a day, with a small hair-pencil, if too much irritation should not be produced. In some subjects, when the eyes are very irritable, and cannot bear the latter applications, Scarpa has found the oil of walnuts a useful application. But it is generally necessary to persevere, at least three or four months, before the case can be reckoned incurable.

All the expedients proposed for the inveterate albugo or leucoma from a cicatrix, consisting of scraping or perforating the layers of the cornea, and exciting ulceration there, are unavailing. For, though the enlargement of the cornea should be lessened by such means, its diaphanous state could not be restored; or should the patient perceive a ray or two of light immediately after the operation, the benefit would only be transient; for as soon as the wound had healed, the opacity would recur. The formation of an artificial ulcer might prove useful, if leucoma depended on

a mere extravasation of lymph; but the fact is, the disease arises from the deposition of an opaque substance, and the disorganization of the texture of the cornea, conjointly: in this lies the difference between albugo and leucoma.

See *Scarpa sulle Malattie degli Occhi*, 8vo. *Venezia*, 1802. *Richter*, *Anfangsgründe der Wundarzn. b.* 3. *Essays on the Morbid Anatomy of the Eye, by J. Wardrop*, *Edin.* 1808, *chap.* 11.

LIGATURE. In the article *Hemorrhage*, it has been explained, that the immediate effect of a tight ligature on an artery, is to cut through its middle and internal coats, a circumstance that tends very much to promote the adhesion of the opposite sides of the vessel to each other. Hence I think with Dr. Jones, in opposition to Scarpa, that the form and mode of applying a ligature to an artery should be such as are most certain of dividing the above coats of the vessel in a regular manner. A broad flat ligature does not seem likely to answer this purpose well, because it is scarcely possible to tie it smoothly round the artery, which is apt to be thrown into folds, or to be puckered by it, and consequently to have an irregular bruised wound made in its middle and internal coats.—(*Jones.*) A ligature of an irregular form is likely to cut through these coats more completely at some parts than others; and if it does not perfectly divide them, though adhesion may yet take place, it is a slower and less certain event, and secondary hemorrhage more likely to follow. The fear of tying a ligature too tight may often lead to the same disadvantages. These and many other important circumstances are noticed in the article *Hemorrhage*.

Ligatures are commonly made of inkle, and rubbed with white wax. They should be round, and very firm, so as to admit of being tied with some force, without risk of breaking.—(See *Jones on Hemorrhage*, *p.* 172.)

The principles which should guide the surgeon in the use of the ligature were not known until the late Dr. Jones published his valuable treatise on hemorrhage. As an able surgeon has observed, "he has banished (at least in this country) the use of thick and broad threads, of tapes, of reserve ligatures, of cylinders of cork and wood, linen compresses, and all the contrivances which, employed as a security against bleeding, only served to multiply the chances of its occurrence."—(*Lawrence, in Med. Chir. Trans. vol.* 6, *p.* 162.)

In the article *Amputation*, I have noticed the method of cutting off both ends of the ligature close to the knot, on the face of the stump, with the view of lessening the quantity of extraneous matter in the wound, and promoting a complete union of the divided parts, without suppuration.

This plan has been tried by Mr. Lawrence: "The method I have adopted (says this gentleman) consists in tying the vessels *with fine silk ligatures*, and cutting off the ends as close to the knot as is consistent with its security. Thus the foreign matter is reduced to the insignificant quantity which forms the noose actually surrounding the vessel, and the knot by which that noose is fastened. Of the silk which I commonly employ, a portion sufficient to tie a large artery, when the ends are cut off, weighs between one-fiftieth and one-sixtieth of a grain: a similar portion of the thickest kind I have tried, weighs one-twentieth of a grain, and of the slenderest one-eightieth."

The kind of silk twist which is commonly known in the shops by the name of dentists' silk, and which is used in making fishing lines, is the strongest material, in proportion to its size, and therefore the best calculated for our purpose, which requires considerable force in drawing the thread tight enough to divide the fibrous and internal coats of the arteries. This twist is rendered very hard and stiff by means of gum, which may be removed by boiling it in soap and water; but the twist then loses a part of its strength. The stoutest twist which Mr. Lawrence has used, is a very small thread, compared with ligatures made of inkle. The quantity of such a thread, necessary for the noose and knot on the iliac artery, weighs one-twentieth of a grain; or, if the gum has been removed, about one-twenty fifth. But the finest twist kept in the silk-shops is strong enough, in its hard state, for any surgical purpose; and the noose and knot, according to Mr. Lawrence's statement, would not weigh one-fortieth of a grain.

It farther appears from the report of this gentleman on the subject, that there is no danger of these ligatures cutting completely through the vessel, as some surgeons have apprehended; and that, although he has not yet ascertained what becomes of the pieces of ligature after the wound is united, he has never seen abscess nor any other bad symptom occasioned by them. At the time when Mr. Lawrence wrote, he had employed this method of securing the arteries in ten or eleven amputations, in six operations on the breast, and in the removal of two testicles. The cases all did well, excepting a man who lost his thigh, and who died of an affection of the lungs.—(See *Lawrence on a New Method of Tying the Arteries in Aneurism, &c. in Medico-Chir. Trans. vol.* 6, *p.* 156, *&c.*)

The foregoing method was tried by myself in several amputations, which I performed in 1815 at Brussels, and in a larger number of cases by my friend Mr. Collier. Our ligatures, however, though small, were not so small as those judiciously recommended by Mr. Lawrence; and on this account, no accurate inferences can be drawn from our examples, which, however, as far as I could learn, were not unfavourable to the practice.

This subject was mentioned by Mr. Guthrie as follows: "Some military surgeons, both French and English, have lately adopted the practice of cutting off both ends of the ligatures close to the knot on the artery; uniting the parts, if possible, over them, and allowing the knots to find their way out as they can. The edges of the wound in some instances, have united thoroughly in a few days; and when the knots have come off the ends of the arteries, they have caused small abscesses to be formed, which point at the nearest external surface, and are discharged with little uneasiness. I know that many cases treated in this manner, in the campaign of 1813, ended successfully, and healed in as short a time as the most favourable ones by the usual method; and at Montpellier, in June, 1814, Mons. Delpech, professor of surgery in that university, showed me at least twenty cases, in which he had practised, and was still practising, this method with success. I have seen, however, in two or three instances, some ill-looking abscesses formed by them, and I suspect some disagreeable consequences will ensue, if this practice be continued.

"I consider this improvement as very valuable in all cases that will not unite by the first intention. The ligatures, if there be many, form into ropes, are the cause of much irritation, and are frequently pulled away with the dressings: by cutting them off, these evils are avoided, and the knots will come away with the discharge."—(*On Gun-shot Wounds of the Extremities*, *p.* 93, 94.)

With respect to the abscesses which this gentleman saw produced by the method, it is properly observed by Mr. Lawrence, that as this statement is not accompanied by any description of the materials or size of the ligature, nor by any details of the unfavourable cases, we cannot judge whether the events alluded to are to be attributed to the method itself, or to the way in which it was executed.—(See *Med. Chir. Trans vol.* 6, *p.* 171.)

M. Roux tried the plan in three operations on the breast: the cases did well, and no ill consequences arose from the presence of the bits of thread under the cicatrix.—(See *Relation d'un Voyage fait à Londres en* 1814, *ou Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise*, *p.* 134—136. *Paris*, 1815.) Mr. Fielding, of Hull, admits that this method occasions less irritation in the first instance, than the usual mode of leaving one or two ends of silk attached to the knot, and bringing them out of the wound, and that union by the first intention is thus more certainly effected; but he assures us, that in a great variety of cases, in which he has adopted the practice, the knots of silk were not absorbed, and were ultimately thrown off unchanged, after a slow suppuration, attended with pain and irritation for several weeks or months.—(See *Edinb. Med. Chir. Trans. vol.* 2. *p.* 341.) Ligatures of silk-worm gut, according to his experience, do not lead to the above inconveniences.—(See *Amputation*, *Aneurism*, and *Hemorrhage*.)

[The plan of Mr. Lawrence here recommended, of using ligatures made of *fine silk twist*, and cutting off the ends as close to the knot as is consistent with its security, is liable to many objections, and the young

surgeon will repent it if he adopt this method indiscriminately. He will not only be liable to be often perplexed with secondary hemorrhage, but those "*ill-looking abscesses*," to which Mr. Guthrie refers, will often retard, and may prevent the union of the divided parts. Indeed, the attempts made in this country have demonstrated, that this practice is less safe and less successful than the old but sure method, of leaving one end of the ligature pendent from the wound.

Where resolution is not expected nor desirable, the practice is less exceptionable; and in certain amputations or gun-shot wounds, where the escape of these knots is easy from the exposed condition of the stump, this method may be safely adopted. But in wounds made by the surgeon for securing arteries which are deep-seated, and where union by the first intention is often important, the old method is greatly to be preferred. Some of the most distinguished surgeons in this country, after having repeatedly tried Mr. Lawrence's plan, with attention to all the minute particularity which he so judiciously enjoins, as regards the size and material of the ligature, have laid it aside altogether, and prefer always to leave the end of their ligatures hanging from the wound or stump. Among these is Professor Mott, of New-York.

To our distinguished countryman, Professor Physick, of the University of Pennsylvania, is undoubtedly due the honour of having first introduced what is known as the *animal ligature* into surgical practice. His ligatures are made of chamois leather, and he and the late Dr. Dorsey usually rolled their ligatures on a slab to make them hard and round. The advantages proposed by the ligatures of Dr. Physick are, that, being made of animal matter, the knot, which is all that is left in the wound, will serve long enough to obliterate the artery, and be speedily removed by the absorbents, thus avoiding the difficulty arising from a foreign body however minute. These ligatures have been used in this country to great extent, and Sir Astley Cooper has demonstrated their superiority in his own operations. Dr. Hartshorn used strips of parchment for his ligatures. My friend, Dr. H. G. Jamieson, professor of surgery in Washington Medical College, Baltimore, has for a series of years been employing the animal ligature in an extensive surgical practice; a number of his operations I have witnessed. He has used it in many amputations of the limbs and the mamma: he has tied the carotid, the iliac, the femoral, the radial, the posterior tibial, the spermatic, and other arteries, with the buckskin ligatures; and in no instance had secondary hemorrhage; and he states that he has never seen any thing of his ligatures, and of course his wounds have generally healed by the first intention.

Dr. Jamieson gives to Dr. Physick the honour of having first introduced the animal ligature; but he contends that the practice of rolling or drawing, to harden the leather, is highly reprehensible. He advises to tie the artery with a buckskin ligature very soft, and a little broader than the thickness of the skin, taking care not to tie it too tight. He states, as the result of his observation and experiments upon sheep, dogs, and other animals, that a capsule will surround the ligature, if the capillary vessels be not much disturbed, or the vessel will be surrounded by an abundance of lymph, and the ligature dissolved

The method of Ætius and Celsus, revived by Abernethy, of applying two ligatures and dividing the artery between them, Dr. Jamieson condemns as unnecessary, since by a single flat buckskin ligature the artery may be obliterated *without destroying its continuity*. Hence he opposes all indissoluble ligatures of whatever material: he declares it not only to be unnecessary, but highly hazardous, to cut the inner coats of the vessel, as recommended by Jones, &c.; and agrees with Scarpa as regards flat ligatures; but by the use of the buckskin, has no need like him to remove his ligatures on the fourth day.

For a very able and interesting account of his views, which are of the highest practical importance, I would refer to the 37th number of the Medical Recorder, published at Philadelphia, for January, 1827. This valuable paper is entitled, "*Observations upon Traumatic Hemorrhage, illustrated by Experiments upon Living Animals. By Horatio G. Jamieson, M. D., Surgeon to the Baltimore Hospital.*" This essay obtained the premium offered for the best paper on suppression of hemorrhage.—*Reese.*]

[The evils of *reserve ligatures* are so generally known, that no chance exists of their ever being resorted to again by any well-educated surgeon. Mons Delpech, professor of surgery at Montpellier, has completely abandoned them, though (in common with the continental surgeons) once a great advocate for their use. The disastrous consequences of these superfluous ligatures, he has been taught by fatal experience Some of the cases he has recently published demonstrate, that nothing is so likely as reserve ligatures to cause ulceration of the artery and secondary hemorrhage. He however is a zealous advocate for the principles and practice of Dr. Jones, and strongly insists on the propriety of letting ligatures cut through the inner and middle coats of the tied vessels.—(See *Chir. Clinique, t.* 1. *Obs. et Réflexions sur la Ligature des Principales Artères*)—*Preface.*]

LINIMENTUM ACIDI SULPHURICI.—℞. Olei olivæ, ℥iss. Acid. sulph. ℥ss. M. Recommended by Mr. Brodie for the removal of the effects of inflammation of the synovial membrane.—(See *Joints.*)

LINIMENTUM AMMONIÆ FORTIUS.—℞. Liq ammon. ℥j. Olei olivæ, ℥iij. Misce. Properties stimulating.

LINIMENTUM CALCIS.—℞. Aquæ calcis, olei olivæ, sing. ℥viij. Spirit. vinosi rectificati, ℥i. Misce A common application to burns and scalds.

LINIMENTUM CAMPHORÆ COMPOSITUM.—℞. Camph. ℥ij. Aq. ammon. ℥vj. Spirit. lavend. ℥xvj. Sixteen ounces are to be distilled of the last two ingredients, from a glass retort, and the camphor then dissolved in the distilled fluid. For bruises, sprains, rigidities of the joints, incipient chilblains, &c.

LINIMENTUM CAMPHORÆ ÆTHEREUM.—℞. Camphoræ drach. j. Ætheris unc. ss. Olei viperarum drach. ij. Misce. The camphor is to be dissolved in the ether, and the oil afterward incorporated with it. The late Mr. Ware sometimes used this application in certain obscure affections of the eye, in which it was not easy to determine whether the imperfection of the sight proceeded from an incipient cataract, or a defect of sensibility in the optic nerve. The outside and edges of the eyelids were rubbed with it every morning and evening, for two or three minutes.

LINIMENTUM HYDRARGYRI COMPOSITUM.—℞. Ung. hydrargyri fortioris, adipis suillæ, sing. ℥i. Camph. ℥ij. Spirit. vinos. rectif. ℥ij. Liq. ammon. ℥j. The camphor being dissolved in the spirit of wine, add the liq. ammon. and the ointment previously blended with the hog's lard.—(*Pharm. Sancti. Barthol.*) An excellent formula for all surgical cases in which the object is to quicken the action of the absorbents and gently stimulate the surfaces of parts. It is a capital application for diminishing a chronic indurated state of particular muscles, every now and then met with in practice; and it is particularly well calculated for lessening the stiffness and chronic thickening of joints.

LINIMENTUM IODINÆ.—℞. Lin. sapon. c. ℥j. Tinct. iodinæ, ℥j. Misce.—(See *Manson's Researches on the Effects of Iodine, p.* 451.)

LINIMENTUM POTASSÆ SULPHURETI.—℞. Saponis albi, ℥iv. Olei amygdalæ, ℥viij. Potassæ sulphureti, ℥vj. Olei Thymi, gr. xv. vel. ♋j. This liniment, used twice a day, will cure the itch in five days, or, at latest, in eight. It has not a very unpleasant smell, and would be preferable to sulphur ointment, if equally efficacious.—(See *London Medical Repository, vol.* 3, *p.* 242; *and Cross's Sketches of the Medical Schools of Paris, p.* 176.)

LINIMENTUM SAPONIS COMPOSITUM.—℞. Sapon. ℥iij. Camph. ℥j. Spirit. rorismar. ℔j. Dissolve the soap in the spirit, and then add the camphor. Uses, the same as those of the linimentum camph.

LINIMENTUM SAPONIS CUM OPIO.—℞. Lin. sapon. comp. ℥vj. Tinct. opii, ℥ij. Misce. For dispersing indurations and swellings attended with pain, but no acute inflammation.

LINIMENTUM TEREBINTHINÆ.—℞. Ung. resinæ flavæ, ℥iv. Ol. terebinthinæ, q. s. Misce. The well-known application for burns, recommended by Kentish.—(See *Burns.*)

LINIMENTUM TEREBINTHINÆ SULPHURICUM.—℞. Olei olivæ, ℥x. Ol. terebinth. ℥iv. Acidi Sulph. ℥iij. Misce. Said to be efficacious in chronic affections of the joints, and in the removal of the old effects of sprains and bruises.—(*Pharm. Chirurgica.*)

LIP, CANCER OF.—The lips are subject to ulcers, which put on a very malignant aspect, although some of them are not in reality malignant; and many, situated just on the inside of these parts, will be found to depend on the bad state of the constitution, and the irritation and disturbance which the sores are continually suffering from the incessant motion of the parts, and their rubbing against a projecting or rough tooth.

The continual irritation, arising from the introduction of food, the effort of speaking, and the constant flow of saliva (as Mr. Earle remarks), are sufficient to keep up the morbid disposition, and to prevent any reparative effort of nature from being carried into effect. After a time, the neighbouring glands will often become enlarged, which confirms the surgeon in the opinion he had been induced to form of the nature of the affection.—(See *Med. Chir. Trans. vol.* 12, *p.* 272.) It is not an uncommon belief, that the irritation of tobacco-pipes frequently gives rise to malignant and even truly cancerous diseases of the lip. The use of cigars may have the same effect.—(See *vol. cit. p.* 278.)

Arsenic is frequently useful in subduing the obstinacy and malignity of certain ulcers and diseases of the lip reputed to be cancerous.—(*Stark, De Cancero Labii Inferioris.*) Of this essay, Professor Laugenbeck speaks in high terms. The following formula is recommended. "℞. Arsenici albi drachm. dimid. Aq. comm. stillaticiæ unc. sex. M. Digerantur vase vitreo causo in balneo arenæ justi caloris ope per horas sex, tum adde potassæ Carbonatis puræ drachm. dimid. antea solut. in Aq. Cinnamon. simpl. unc. duab. M. Digerantur denuo per aliquot horas in loco temperato. Hac solutione bis terve quotidie ad guttas 8—10—15, utimur."

When cancer takes place, it is usually in the lower, and very seldom in the upper lip. Sir A. Cooper has seen but one instance in the latter part.—(*Lancet, vol.* 3, *p.* 109.)

The disease sometimes puts on the appearance of an ulcerated wart-like excrescence, occasionally acquiring a considerable size. Sometimes it is seen in the form of a very destructive ulcer, which consumes the surrounding substance of the lip; and in other examples the disease resembles a hard lump, which at length ulcerates. The disease, in its infancy, is often no more than a pimple, which gradually becomes malignant. As the disease advances, the glands under the jaw enlarge. According to Mr. Travers's observations, cancer of the lower lip begins in the cellular tissue between the mucous membrane and the skin. The enlargement and induration, he says, render it conspicuous before the villous surface of the lip cracks transversely, and a thin fluid oozes: it then exulcerates and scabs by turns, and ultimately penetrates more deeply, and throws out a fungus. The patient is generally a healthy male of advanced years, and accustomed to smoking. Pus sometimes escapes when the fungus is divided; but the base of the tumour is hard and granular. The skin and mucous membrane, and the labial glands, now prominent and warty, form a close compact mass. As the ulceration proceeds, the induration extends, and the salivary glands, and the lymphatic glands at one or both angles of the jaw, become enlarged and tender.—(*Travers, in Med. Chir. Trans. vol.* 15, *p.* 239.) Whenever there is reason to believe that the disease is of an unyielding cancerous nature, and it does not soon give way to arsenic, iodine, hemlock, or mercurials, the sooner it is extirpated the better. For this purpose some surgeons admit the propriety of using caustic when the whole disease can be completely destroyed by one application. But as the action of caustic is not capable of being regulated with so much precision as the extent of a wound can be, and as caustic will not allow the parts to be united again, the knife is the only justifiable means, especially as it also occasions less pain. Two incisions are to be made, meeting at an angle below (supposing it to be the lower lip), and including the whole of the disease. The sides of the wound are then to be united by the twisted suture.—(See *Harelip.*) When the affection is extensive, however, the surgeon is frequently necessitated to remove the whole of the lip, or too much of it to admit of the above plan being followed. This circumstance has generally been regarded as particularly unfavourable: and it has been commonly believed, that unless some attempt can be made to succour the patient by the Taliacotian practice, in the manner mentioned by Mr. Earle (*Med. Chir. Trans. vol.* 12, *p.* 276), the patient's spittle would continually run over his chin, or only admit of being kept from doing so by some artificial contrivance. It was also thought that the deformity would be very great, and that pronunciation and swallowing would be but imperfectly performed. Some observations lately published by Mr. Travers, however, tend to prove that these disadvantages have been exaggerated; and, convinced of the prudence of a free removal of the disease in its early stage, he prefers "a full crescent-shaped section of the substance of the lip" to an operation resembling that for the cure of a harelip. He recommends the commissure of the mouth to be spared, if possible. "The contraction during the healing process under a double-headed bandage, passing over the vertex and occiput, so as to keep a little moistened lint or simple ointment on the cut surface, shapes and adapts the lip with singular neatness; and what is more remarkable, the cut surface takes a depth of colour and a plumpness, and a defined border, which give much the appearance of the natural surface." In one case of malignant ulcer, published by Mr. Earle, he removed the angle of the mouth and a large portion of each lip, together with a considerable part of the cheek, yet succeeded in uniting the wound, which object was facilitated by the extraction of five teeth from the lower jaw previously to the operation, which were useless in consequence of having no corresponding ones in the upper jaw.—(*Med. Chir. Trans. vol.* 12, *p.* 274.)

LIPPITUDO. (From *lippus*, blear-eyed.) *Blearedness.* The ciliary glands and lining of the eyelids only secrete in the sound state just a sufficiency of a sebaceous fluid to lubricate the parts in their continual motions. But it sometimes happens from disease that this sebaceous matter is secreted in too great a quantity, and glues the eyelids together during sleep, so that on waking they cannot be easily separated. Hence the margin of the eyelids becomes red all round, and the sight itself even weakened.

The best remedies are the unguentum hydrargyri nitrati smeared at night on the edges and inside of the eyelid with a hair pencil, after being melted in a spoon the unguentum tutiæ, applied in the same way; and a collyrium, composed of ℈j. of the sulphate of zinc in ℥viij. of rose water.

When alterative medicines are requisite, a grain of calomel may be exhibited daily, or the compound calomel pill, containing one grain of calomel, one of sulphur antimonii præcipitatum, and two of guaiacum, put together with soap.

Persons who have lippitudo and cataracts together, bear couching much better than one would expect from the appearance of the eyes; and Mr. Hey never rejected a patient on this account, provided such state were habitual.—(*Pract. Obs. p.* 51.) Scarpa, however, recommends the lippitudo to be removed before the operation is undertaken.

LIQUOR AMMON. ACET. (L. P.)—This is given in the dose of half an ounce in many surgical cases, in which the object is to keep up a gentle perspiration.

LIQUOR ARSENICALIS.—℞. Arsenici Oxydi præparati in pulverem subtilissimum triti, Potassæ Subcarbonatis ex tartaro singulorum gr. 64. Aq. distill. ℔j. coque simul in vase vitreo, donec arsenicum omne liquetur. Liquori frigefacto adjice Spiritûs Lavandulæ com. ℥iv. Denique adjice insuper Aq. distil. quantum satis sit, ut mensuram octarii accurate impleat. For internal use the dose is iv. drops gradually increased to xx. twice a day. It is frequently given in cases of anomalous ulcers, and cancerous affections of the lip. It is also used as an external application in similar cases, and especially in hospital gangrene.—(See *Arsenic* and *Hospital Gangrene.*)

LIQUOR CALCIS (L. P.)—Sometimes used as an astringent injection or lotion; also in gargles; it has been given internally as a lithontriptic.

LIQUOR CUPRI SULPHATIS CAMPHORATUS.—℞. Cupri sulphatis. Boli Gallici sing. unc. ss. Camphoræ drach. j. Aquæ ferventis, lib. iv. Boiling water is to be added to the other ingredients, and the liquor filtered when cold. It is chiefly employed in a diluted state as a collyrium; but it may also prove of service as an application to foul ulcers.

When used for the cure of the purulent ophthalmy, the lotion is to be injected under the eyelids by means of a blunt syringe; and if necessary, the application may be repeated once or twice every hour.—(See *Ophthalmy.*)

LIQUOR POTASSÆ (L. P.)—Has been given with the view of dissolving stone in the bladder.—(See *Urinary Calculi.*)

The dose is from ten to twenty drops, twice a day, in some linseed tea, veal broth, or table beer. It has been found useful in lepra, psoriasis, and some other cutaneous diseases.—(See *Paris's Pharmacologia, vol. 2, p. 281, ed. 5.*)

LIQUOR POTASSÆ SUBCARBONATIS (L. P.)—This remedy is principally deserving of notice on account of its having been given to dissolve calculi in the bladder, so as to remove the necessity of performing the dangerous and painful operation of lithotomy. It may be exhibited in doses of 20 or 40 drops, or of a drachm, in a basin of gruel. Experience does not seem to justify the indulgence of much hope with regard to the complete efficacy of the medicine in dissolving urinary calculi, and on some kinds it is not calculated to act at all even on chemical principles; but it would appear from the reports of writers, that it has often materially palliated the pain which attends the presence of a stone in the bladder.—(See *Urinary Calculi.*)

LIQUOR POTASSÆ ARSENICATÆ.—℞ Potassæ arsenicatæ, grana duo. Aquæ menthæ sativæ uncias quatuor. Spiritus vinosi tenuioris unciam. Misce et cola. Two drachms of this may be given thrice a day in cases of cancer. My friend, Mr. Barnes, of Exeter, once showed me a lupus, or noli me tangere, which was greatly benefited by this remedy externally applied. He was using the lotion with double the proportion of arsenic. Certain ulcerations about the roots of the nails of the fingers and toes, to which Plunket's caustic is sometimes applied might be much benefited by this lotion, which is certainly a neater application.

LIQUOR PLUMBI ACETATIS—Is used, largely diluted with water, as a common application to inflamed parts.—(See *Inflammation.*) One drachm to a quart of water is quite strong enough for common purposes. Mr. Justamond and Dr. Cheston used to apply it, mixed with an equal proportion of a spirit resembling the tinctura ferri muriati, to the edges of cancerous sores.

LITHONTRIPTICS. (From λίθος, a stone; and θρύπτω, to break.) Medicines for dissolving stones in the bladder.—(See *Urinary Calculi.*)

LITHONTRIPTOR. The name of an instrument for reducing calculi in the bladder into small particles or a powder, which is voided with the urine, and lithotomy thus rendered unnecessary. According to some accounts, it was invented by M. Le Roy d'Etioles, but first brought into much notice by the exertions of Dr. Civiale of Paris. It is not for me to enter into the dispute concerning the degree of merit which may belong in this subject to each of these gentlemen, or to Baron Heurteloup, who has warmly defended the priority of M. Le Roy's claim, at the same time that he has himself contributed very much to the perfection of the instruments and the success of the practice. The lithontriptor consists of a straight silver catheter of considerable diameter, and enclosing another of steel, the lower extremity of which consists of three branches, calculated to grasp the stone on withdrawing the steel catheter a short way within the outer one, when they become approximated. The cavity of the inner catheter is capable of admitting a steel rod, to which may be affixed, at the surgeon's option, a simple quadrangular drill, or a strawberry-shaped file, or a trephine. By means of a spring the latter part of the apparatus is pressed evenly inwards, and it is made to revolve with velocity through the medium of a bow, after the manner of a common hand-drill. Chaussier and Percy were requested by the Royal Academy of Medicine at Paris to examine the merits of this new invention, and to draw up a report on the subject. "This report (as a respectable journal states) speaks in very strong terms of the success which the reporters witnessed in repeated trials by the inventor; and there can be no doubt, from the distinct and precise evidence adduced by them, that none of the means previously suggested for the same purpose can compete with the instrument now proposed. The first case in which the reporters witnessed its application, was that of a man thirty-two years old, who had a mulberry calculus of considerable size. The experiment was made in presence of Chaussier, Percy, Larrey, and several other surgeons of eminence. The instrument having been introduced, and the stone caught at the first attempt, 'at every stroke of the bow those present heard a crackling sound, which announced both the hardness of the stone and the rapidity of its demolition.' The operation was continued at occasional intervals for forty minutes, during which the patient complained rather of uneasiness than of decided pain. The instrument was then withdrawn, and the patient immediately discharged with his urine a quantity of powdery detritus, which was supposed to form a third part of the stone. The operation was renewed eleven days afterward, in presence of the same persons, and of Magendie and Serres; and again, a third time, ten days afterward. The quantity of powdery matter then discharged appeared to be equivalent to the size of the stone, and no calculus could be afterward discovered in the bladder by the most careful sounding. The second case was that of a man affected with a calculus, of which the nucleus was a kidney-bean. The urethra had been previously dilated by the successive introduction of sounds of larger and larger diameters. The sound caused in this instance was dull and obscure. The bladder being irritable and disposed to contract, the operation was continued for a shorter period than in the former case, and was resumed every third day. Four operations removed the whole of the stone, the patient being sounded after the fourth by one of the most dexterous lithotomists in Paris. The stone in this case came off in sundry particles, and little fragments loosely agglutinated by a viscous animal matter. At the third operation the forceps caught and brought away the bean, deprived of its epidermis; and at the next, the crust came away with the remaining fragments of the stone. In the third case, the stone was of the size of a pigeon's egg, and moderately hard. After three operations, the cure, at the period of the delivery of the report, was considered as nearly completed. Nothing unusual occurred in this case, except that, on one occasion, the operator failed in catching hold of the stone. The plan is evidently inadmissible when the stone is too large to be seized with the forceps, when it is adherent, encysted, or formed on a nucleus of a metallic or bony nature."—(See *Arch. Gén. de Méd. May*, 1824; and *Edinb. Med. and Surg. Journ. Jan.* 1825.)

In 1813, a German surgeon, Gruithuisen, conceived, as Desault had done long ago for calculi in the urethra (see *Lithotomy*), that the principle of the common bullet-forceps might be adopted in the construction of an instrument for taking hold of stones in the bladder; and he accordingly formed an instrument consisting of a straight cannula of the diameter of four lines, and a central steel rod terminating in three elastic claws or tenacula, which might be thrust forwards in search of the calculus, and drawn back to grasp it. Gruithuisen's merit in the invention, however, extends farther than this; for he first demonstrated the practicableness of introducing a tube that was nearly straight through the urethra into the bladder, whereby the facility of lithontriptic measures may be said to have been first made manifest. He also suggested comminuting the stone with an iron rod introduced through the tube.

In 1823, Dr. Le Roy added to the claws of Gruithuisen's instrument a drill for destroying the stone when grasped. But of late the apparatus has been brought to great perfection, partly by M. Civiale and partly by Baron Heurteloup. The latter remarked, when he was in London, that his instrument would not at present entirely supersede the lateral operation, as it was not adapted to destroy a larger stone than one of eighteen lines diameter; but that a more attentive regard to the diagnosis of this painful disease would, in future, by ensuring the discovery of calculi while small, render a recourse to the knife perfectly needless. The steps of the process are the following:

1st. The injecting of the bladder with warm water, which is done by means of a catheter furnished with a stop-cock, and a large syringe made for the purpose.

2d. The indicating the situation of the stone; the catheter already introduced serves the purpose of a sound; its short curve very much facilitates the detection of calculi.

3d. The seizure of the stone. This is done by the claws of the instrument.

4th. The perforation by Le Roy's drill.

5th. The excavation, effected by an instrument shortly to be described.

6th. The crushing and pulverization of the shell, effected by an instrument to be described, called the "shell-breaker."

7th. The ejection of the powder by the contractile force of the bladder.

8th. For small stones and flat stones the "shell-breaker" only is used.

Baron Heurteloup employs an operation bed or table, about the height of our ordinary operation tables, covered with a mattress, which may be raised into an inclined plane, and supported by a wedge-shaped box. At the foot of this bed there is an apparatus which affords a fulcrum to the instrument after its introduction into the bladder. The head of the bed, and consequently the fundus of the bladder, may be depressed to any extent desired, the legs which support it being hinged and capable of folding under. On this couch the man is placed nearly in the position for the lateral operation. A strap is passed round the shoulders and buckled to the sides; the feet are placed in slippers securely fixed at the foot of the bed.

The Baron, when he was in England in 1829, showed the following instruments to the London surgeons.

1st. The catheter of the usual length, with a short and rather abrupt curve to serve as a sound; the shortness of the curve facilitating its motions in the bladder: it is furnished with a stop-cock.

2d. The syringe of silver, capable of containing about a pint of fluid; furnished with two rings, one on each side of the syphon, for the insertion of two fingers, rendering it manageable with one hand only.

3d. "*L'instrument à trois branches, avec un foret simple*," designed by Le Roy, adopted by Civiale, consisting of a cannula, three tenacula, and the drill. This suffices to crush stones equal in diameter to the drill; but to destroy a larger stone several perforations are necessary, which consume a great deal of time, and some risk is incurred from the entanglement of the claws. To obviate these difficulties, the Baron has devised the following means:—

4th. "*L'instrument à trois branches, avec le mandrin à virgule*" is applicable to stones of from eight to ten lines in diameter. By an ingenious contrivance, a shoulder ("*la virgule*") is thrown out sideways from the head of the drill, and in its revolution excavates the calculus. For stones of larger diameter another contrivance is produced.

5th. "*L'instrument à quatre branches*," or "*pince à forceps.*' Here are four claws, forceps-shaped, which may be moved conjointly or separately, so as to obviate every change of entanglement. One of the claws has a button-point, and may be thrust farther forwards than the rest, and prevent (in case the fluid escape) the bladder from embracing the instrument too closely. The "*pince à forceps*" is adapted to stones of from twelve to eighteen lines in diameter, and is furnished with a "*mandrin à virgule*," the "*virgule*" of which makes a larger excavation. In case the stone, or a fragment of it, should escape from the claws of the "*pince*," the fruitful imagination of the Baron has supplied a remedy: the "*mandrin*" is withdrawn, and a very delicate instrument, consisting of a cannula, a steel rod, and three very fine elastic tenacula, is introduced, the substance is seized and replaced within the jaws of the larger instrument, and the process of its destruction is resumed. The prehensile property of this little instrument is truly admirable. The "*pince à forceps*" consists of nineteen different pieces.

6th. To break down the shell thus formed, as well as small and flat stones, with facility, another contrivance was necessary. To fulfil this intention, the Baron has constructed an instrument which may be termed his master-piece. "*Le brise coque*," or "shell-breaker," is very complicate in its structure, consisting of not less than twenty-five pieces. Its primary essential parts appear to be two parallel steel rods, contained in a circular silver cannula about the third of an inch in diameter: the extremities of these rods, when thrust forwards from the cannula, expand by their own elastic force, and are seen to be forceps-shaped and serrated: the stone is grasped with facility, by a motion similar to the lateral motion of the jaw, and ground to powder in a few minutes. The machinery by which this is effected is concealed from view. The facility of using the "*brise coque*" is, however, very evident; after its introduction, the instrument is held in the left hand, and the effect desired is produced by a movement of the handle from side to side by the right hand.

The Baron showed in London the effects of these different instruments on artificial calculi. On the 24th of July, 1829, he operated on a patient sixty-four years old; at the house of Mr. White: the stone was about fourteen lines in diameter, and the operation was concluded in fourteen minutes.—(See *Lancet*, 1828-29, *p.* 568, *&c.*) It must not be supposed that the lithontriptor gives no pain; for in several instances this has been so severe as to make the patient refuse to submit to the experiment again; and I have heard it calculated that six repetitions of the application sometimes cause as much suffering as lithotomy. But on this estimate the difference is much against the latter; while the former does not endanger life, as lithotomy always does, and this even with the most skilful operators. The lithontriptor, as the foregoing account proves, will effect the removal of much larger calculi than can be drawn out with the urethral forceps made by Mr. Weiss (see *Lithotomy*), and, in this respect, is superior to the latter instrument, and a truly great improvement. But for other cases, in which the calculi are numerous, and not too large to be drawn out in an unbroken state through the urethra, the urethral forceps may merit the preference.

LITHOTOMY. (From λίθος, a stone, and τέμνω, to cut.) The operation of cutting into the bladder, in order to extract a stone.

It has been correctly remarked, that no single operation of surgery has attracted so much notice, or had so much written upon it, as lithotomy. A full and minute account of the sentiments of every writer who has treated of it, and a detail of the infinite variety of particular modes of making an opening into the bladder, would occupy as many pages as are allotted to the whole of this Dictionary. It must be my endeavour, therefore, rather to describe what is most interesting and important, than pretend to offer an article which is to comprehend every thing.

Throughout the following columns, I suppose the reader to be already well informed of all that relates to the anatomy of the bladder and adjacent parts, and that of the perineum. Without correct knowledge of this kind, a man must be presumptuous indeed to set himself up for a good lithotomist; and if he were to distinguish himself at all, it would only be by the murders which he committed, while his successful feats, if he achieved any, could redound little to his honour, since every young student would soon find out that they were not the effect of science but of mechanical habit and imitation. I would particularly recommend every one who wishes to understand well the anatomy of the pelvic viscera and perineum, with a view to lithotomy, in the first place to dissect those parts himself, and then avail himself of the valuable instructions to be derived on the subject from *Winslow's Anatomy; Le Dran's Parallèle de la Taille; Le Cat's Deuxième Recueil, planches* 5 *et* 6; *Haller's Inst. Med. of Boerhaave, and Elém. Physiol. t.* 5; *Morgagni, Adversar Anat.* 3, *p.* 82. 97; *Camper's plates; Lizars's plates; John Bell's Principles of Surgery; Deschamps's Traité Historique, &c. de l' Operation de la Taille, t.*1, *p.* 7, *&c.*; and Langenbeck's description of the parts, and the matchless plate which he has given of them in his valuable work on lithotomy, cited at the end of this article.

A few subjects closely connected with the present will be found in other parts of this Dictionary. For instance, the nature of stones in the bladder will be considered under the head of *Urinary Calculi*, where also will be seen some observations on lithontriptics. The manner of searching for the stone, or as it is now more commonly expressed of sounding, will be explained in the article *Sounding*.

Here I shall principally confine myself to the symptoms of the disease, and the chief methods of executing the much-diversified operation of lithotomy.

SYMPTOMS OF THE STONE.

The symptoms of a stone in the bladder are, a sort of itching along the penis, particularly at the extremity of the glans; and hence the patient often acquires the habit of pulling the prepuce, which becomes very much elongated; frequent propensities to make water, and go to stool; great pain in voiding the urine, and diffi-

culty of retaining it, and often of keeping the feces from being discharged at the same time: the stream of urine is liable to stop suddenly, while flowing in a full current, although the bladder is not empty, so that the fluid is expelled by fits as it were; the pain is greatest towards the end of and just after the evacuation; there is a dull pain about the neck of the bladder, together with a sense of weight or pressure at the lower part of the pelvis: and a large quantity of mucus is mixed with the urine; and sometimes the latter is tinged with blood, especially after exercise.—(*Sharp, Earle, Sabatier.*)

Frequently (says Deschamps) a patient will have a stone in his bladder a long while without the occurrence being indicated by the symptoms.—(See *Case in Hunship on Complaints affecting the Secretion and Excretion of the Urine, p.* 125.) Most commonly, however, the presence of the stone is announced by pain in the kidneys, more especially in adults and old persons; children scarcely ever suffering in this way, because in them the stone is hardly detained in the kidneys and ureters at all, but descends immediately into the bladder.

It seldom happens that calculous patients void blood with their urine before the symptoms usually caused by the stone have taken place. It is not till after the foreign body has descended into the bladder, acquired some size, and presented itself at the orifice of that viscus, that pain is occasioned, particularly when the surface of the stone is unequal. The patient then experiences frequent inclination to make water, attended with pain. The jolting of a carriage, riding on horseback, and much walking, render the pain more acute. The urine appears bloody, and its course is frequently interrupted, and sabulous matter and particles of stone are sometimes discharged with it. The want to make water becomes more frequent and more insupportable. The bladder is irritated and inflames, its parietes become thickened and indurated, and its diameter is lessened. A viscid, more or less, tenacious matter is observed in greater or less quantity in the urine, and is precipitated to the bottom of the vessel. The urine becomes black and putrid, and exhales an intolerable alkalescent smell, which is perceived at the very moment of the evacuation, and is much stronger a little while afterward. The patient can no longer use any exercise without all his complaints being redoubled. Whenever he takes much exercise the urine becomes bloody; the pain about the hypochondria, which was dull in the beginning, grows more and more acute; the ureters and kidneys participate in the irritation with the bladder; they inflame and suppurate, and very soon the urine brings away with it purulent matter. The fever increases, and changes into one of a slow type; the patient loses his sleep and appetite, becomes emaciated and exhausted; and death at length puts a period to his misery.—(See *Traité Historique et Dogmatique de l'Operation de la Taille, par J. F. L. Deschamps, t.* 1, *p.* 163. *Paris*, 1796.)

It is acknowledged by the most experienced surgeons, that the symptoms of a stone in the bladder are exceedingly equivocal, and may be produced by several other disorders. "Pain in making water, and not being able to discharge the urine without the feces, are common consequences of irritation of parts about the neck of the bladder, from a diseased prostate gland, and other causes. The urine stopping in a full stream is frequently caused by a stone altering its situation so as to obstruct the passage; but the same thing may happen from a tumour or fungus in the bladder. I have seen an instance of this, where a tumour, hanging by a small pedicle, would sometimes cause obstruction, and by altering the posture would retire and give a free passage. The dull pain at the neck of the bladder, and the sensation of pressure on the rectum, are frequently owing to the weight of the stone, &c.; but these may proceed from a diseased enlargement of the prostate gland. Children generally, and grown persons frequently, are subject to a prolapsus ani, from the irritation of a stone in the bladder; but it will likewise be produced by any irritation in those parts."—(*Earle.*) The rest of the symptoms are equally fallacious; a schirrous enlargement of the os tincæ and disease of the kidneys may occasion a copious quantity of mucus in the urine, with pain, irritation, &c. "The least fallible sign (says Sir James Earle) which I have remarked, is the patient making the first portion of urine with ease, and complaining of great pain coming on when the last drops are expelled. This may readily be accounted for, from the bladder being at first defended from contact with the stone by the urine, and at last being pressed naked against it. But to put the matter out of all doubt, and actually to prove the existence of a stone in the bladder, we must have recourse to the operation of sounding."

A stone in the ureter or kidneys, or an inflammation in the bladder from any other cause, will sometimes produce the same effects: but if the patient cannot urinate, except in a certain posture, it is almost a sure sign that the orifice of the bladder is obstructed by a stone. If he finds ease by pressing against the perinæum with his fingers, or sitting with that part upon a hard body, there is little doubt the ease is procured by taking off the weight of the stone; or, lastly, if, with the other symptoms, he thinks he can feel it roll in his bladder, it is hardly possible to be mistaken; however, the only sure judgment is to be formed from searching.

An enlarged prostate gland is attended with symptoms resembling those of a stone in the bladder; but with this difference, that the motion of a coach, or horse, does not increase the grievances when the prostate is affected, while it does so in an intolerable degree in cases of stone. It also generally happens, that the fits of the stone come on at intervals: whereas the pain from a diseased prostate is neither so unequal nor so acute.—(*Sharp in Critical Inquiry, p.* 165, *edit.* 4.)

Though from a consideration of all the circumstances above related, the surgeon may form a *probable* opinion of there being a stone in the bladder, yet he must never presume to deliver a *positive* one, nor ever be so rash as to undertake lithotomy, without having greater reason for being certain that there is a stone to be extracted. Indeed, all prudent surgeons, for centuries past, have laid it down as an invariable maxim, never to deliver a decisive judgment, nor undertake lithotomy, without having previously introduced a metallic instrument, called a sound, into the bladder, and plainly felt the stone.

[There are frequently cases in which the symptoms of stone in the bladder are all present, and yet, on examination with the sound, the surgeon will not be able to feel it distinctly, so as to satisfy himself or others. But as the operation should never be attempted until the stone is plainly felt, when any difficulty exists in ascertaining the presence of the calculus, let the patient be placed nearly on his head so as to render the fundus of the bladder the lowest part, and thus bring the foreign body into contact with the point of the sound. This method was first suggested by Dr. Physick, and he has thus detected the existence of calculi, where other surgeons had sounded repeatedly without success.—*Reese.*]

I know of at least seven cases, and at two of them I was present, where the patients were subjected to all the torture and perils of this operation, without there being any calculi in their bladders. The maxim, therefore, cannot be too strictly enforced, that the operation ought never to be attempted, unless the stone can be *distinctly* felt with the sound or staff. In one of the examples, of which I was a spectator, not only the symptoms, but the feel which the sound itself communicated when in the bladder, made the surgeons imagine that there was a calculus, or some extraneous body in this organ. Most of the above cases, I understand, recovered, which may be considered fortunate; because when the stone cannot be found, the disappointed operator is apt to persist in roughly introducing his fingers, and a variety of instruments, so long, in the hope of catching what cannot be got hold of, that inflammation of the bladder and peritoneum is more likely to follow, than when a stone is actually present, soon taken out, and the patient kept only a short time upon the operating table.

In a valuable practical work is recorded an instance, in which what is called a horny cartilaginous state of the bladder made the sound communicate a sensation like that arising from the instrument actually touching a stone, and the surgeon attempted lithotomy. This patient unfortunately died in twenty-four hours.—(See *Desault's Parisian Chir. Journal, vol.* 2, *p.* 125.)

However, were the symptoms most unequivocal, there is one circumstance which would always render it satisfactory to touch the stone with an instrument, just *before* the operation, I mean the possibility of a

stone being actually in the bladder to-day, and *not to-morrow*. Stones are occasionally forced, by the violent contractions of the bladder, during fits of the complaint, between the fasciculi of the muscular coat of this viscus, together with a portion of the membranous lining of the part, so as to become what is termed encysted. Or, as there is reason to believe, the cyst is sometimes produced first, and the calculus is formed in it, as a kind of effect of the existence of the separate pouch. The opening into the cyst is frequently very narrow, so that the stone is much bigger than such orifice, in consequence of which it is impossible to lay hold of the extraneous body with the forceps, and the operation would necessarily become fruitless.—(*Sharp's Critical Inquiry, p.* 228, *edit.* 4.)

In the article *Urinary Calculi*, I have noticed the probability of this having occurred in some of the instances in which Mrs. Stevens's medicine was supposed to have actually dissolved the stone in the bladder: for an encysted stone is not likely to be hit with the sound, nor to cause any inconvenience, compared with what a calculus, rolling about in the bladder, usually occasions.

It is remarked by Deschamps, that when the stone is lodged in an excavated corner of the bladder, in a particular cyst, or depression; when it projects but very little; when it cannot shift its situation in the bladder, so as to fall against the orifice of this viscus; and when it is also smooth, polished, and light; the patient may have it a long while, without experiencing any afflicting symptoms. He may even live to an advanced age, if not without some degree of suffering, at all events, with such pain as is very supportable. Daily experience proves, that persons may live a considerable time, with one, two, or even three stones in the bladder, and during the whole of their lives have not the least suspicion of the existence of these foreign bodies.

According to Deschamps, this must have been the case of M. Portalieu, a tailor. This individual, eighty years old, was frequently attacked with a retention of urine from paralysis, and Deschamps introduced a sound several times, and distinctly felt a stone in the bladder. The patient, however, never had any symptom of the disorder, nor even at the end of two years from the time when Deschamps was first consulted. Very large and exceedingly rough stones have also been found in the dead bodies of persons, who had never complained of the symptoms of the disease. Thus, at the Anatomical Theatre of La Charité, Richerand found an enormous mulberry stone in the bladder of a person, who died altogether of another disease, and never had any symptom that led to the suspicion of the stone.—(*Nosographie Chir. t.* 3, *p.* 530, *edit.* 4.) But cases of this kind must be rare, because it is well known that the pain which a stone produces is less in a ratio to its size than to its shape and situation. A small stone, owing to its situation, may be more painful than an enormous calculus, which fills the bladder, as is proved by the following case by Deschamps.

Pochet, a watchmaker, until the age of forty-five, had never had any infirmity, except that of not being able to retain his water a long while. One day, while he was carrying a very heavy clock, he made some exertions, which, probably, by changing the situation of the calculus, caused at the instant an acute pain in the hypogastric region. Symptoms of the stone soon came on: the pain became intolerable, and the patient went into the Hôpital de la Charité. He was sounded; the stone was felt, and judged to be of considerable size. The incision in the neck of the bladder not sufficing for its extraction, the patient was put to bed again. The next morning, he was operated upon above the pubes by Frère Côme, who extracted an oval calculus that weighed twenty-four ounces. The patient died four-and twenty hours after this second operation. This case proves then that very large stones may lie in the bladder without occasioning any serious complaints, since the preceding patient apparently had had such a calculus a long time, without suffering inconvenience from it, and it seems likely that he might have continued well still longer, had it not been for the accidental effort which first excited the symptoms.—(*Traité Historique, &c. de la Taille, t.* 1, *p.* 166, 167.)

A priest, in whom Morand had ascertained the presence of a stone by sounding, could not be persuaded that his case was of this nature. However, he bequeathed his body at his decease to the surgeons, and the examination of the bladder fully justified Morand's prognosis. The celebrated D'Alembert also died with a stone in his bladder, having always refused to be sounded.—(*Richerand, Op. cit. t.* 3, *p.* 538.)

A question may here suggest itself: ought lithotomy to be practised where calculi are under a certain size? Certainly not, because they frequently admit of being extracted through the urethra, or discharged with the urine, without any operation at all, even from the male subject; and how much more likely this is to happen in females, must be plain to every body who recollects the direct course, the shortness, ample size, and dilatability of the meatus urinarius. On this subject, various facts, and, in particular, the dilator used by Sir A. Cooper, will be adverted to in considering lithotomy in women. Sometimes, also, when a calculus is too large to pass completely through the male urethra, it lodges in this passage, where it may be more safely cut upon and removed, than from the bladder; and sometimes it is actually discharged by an ulcerative process. Thus Dr. R. A. Langenbeck has published an example, in which a stone made its way out by ulceration, and was discharged immediately behind the testes.—(See *J. C. Langenbeck's Bibl. für die Chir. Gött.* 1809.) And G. Coopmans has recorded an almost incredible case, in which a calculus, weighing five ounces one drachm and a half, was discharged on the left side of the urethra of an elderly man, a little below the glans penis. In fact, without some farther explanation, this case would be pronounced impossible; but it should be recollected, that after a small calculus has made its way out of the urethra by ulceration, if the urine have still access to it, it will continue to increase in size in its new situation; and this is what happened in the present example; for the extraneous body, when first felt externally, was not larger than a pea. The calculus is now preserved in Camper's museum.—(*Neurologia*, 8*vo. Franequeræ*, 1795.) I am not meaning, however, to recommend surgeons to let the patient encounter all the sufferings which must inevitably attend leaving the business to be completed by ulceration; because, as soon as the nature of the case is known, an incision should be made into the swelling, and the foreign body taken out. In many cases, also, small calculi may be voided by dilating the male urethra with elastic gum catheters of very large diameter, and then desiring the patient to expel his urine, with considerable force, a plan which Baron Larrey has found repeatedly answer. The idea of withdrawing calculi from the bladder through the urethra by suction and dilatation of the passage, seems to have been entertained by several practitioners of former days, especially Alpinus, Muys, Verduc, Mayerne, and Le Dran.—(See *Dr. Kerrison's Paper in Med. Chir. Trans. vol.* 12, *p.* 315.) Desault even tried experiments with a kind of forceps, which admitted of being protruded, and of opening and shutting at the extremity of a cannula, which was introduced into the bladder; but no instance of his success on the human subject is recorded.—(See *Journ. de Chir. t.* 2, *p.* 375, *Paris*, 1791.) The honour of bringing the plan to perfection was reserved for Sir Astley Cooper: "The instrument (says he) which I first had made for the purpose of removing these stones from Mr. Buller, were merely common forceps, made of the size of a sound, and similarly curved; but Mr. Weiss, surgeons' instrument maker in the Strand, showed me a pair of bullet forceps, which, he thought, would with a little alteration better answer the purpose I had in view. He removed two of the blades of these forceps (for there were four), and gave them the form of the forceps which I had had constructed: the blades of this instrument could be opened while in the bladder, by means of a stilette, so as to grasp and confine the stone, and they appeared so well constructed for the purpose as to induce me to make a trial of them, on the 23d of November, 1820; and the manner in which they were used was as follows: Mr. Buller was placed across his bed, with his feet resting on the floor, and a silver catheter was then introduced, and the bladder emptied of urine. I then passed the forceps into the bladder, and was so fortunate in my first operation as to extract eight calculi. The instrument gave but little pain on its introduction but when opened to its greatest extent, and the stones admitted between its blades, their removal was painful, more especially at the glans penis, which appears to be the portion of the urethra which

makes the greatest resistance to the removal of the stones. A dose of opium was given after each operation."—(*Med. Chir. Trans. vol.* 11, *p.* 358.) Sir A. Cooper thus removed from the above patient 84 calculi at different times. From one patient, Mr. Brodie also extracted in the same manner about sixty calculi, of various sizes; but the largest measured half an inch in one diameter, and five-eighths in the other.—(*Op. cit. vol.* 12, *p.* 383.) In one case, Sir A. Cooper took out with the urethral forceps a calculus that weighed fifty-four grains, after having gradually dilated the urethra with bougies.—(*Vol. cit. p.* 387.) Other convincing examples of the practicableness and success of the practice are also related by the same distinguished surgeon. According to his valuable observations, when a great number of calculi are found in the bladder, they are generally attended with an enlargement of the prostate gland, and are lodged in a sacculus formed directly behind it.—(*Vol.* 11, *p.* 357.)

To me the establishment of the preceding practice by Sir Astley Cooper, and the invention of the lithontriptor, seem two of the greatest triumphs of modern surgery; and I have no doubt that the names of all concerned in bringing them about, will receive from the latest posterity the honour which cannot fail to attach itself to improvements, by which the necessity for a severe and highly dangerous operation is rendered considerably less frequent. Even when the stone cannot be drawn completely out of the urethra by the forceps, but only into it, the advantage is great, because it may then be easily cut down to and extracted without any wound or injury of the bladder.—(See *Med. Chir. Trans. vol.* 11.) And in cases where a calculus is larger than can be extracted by the urethral forceps, but not too large to be seized and pulverized by the lithrontriptor (see *this word*), I am disposed to believe that, except when the stone is above a certain size, the severe and perilous operation of lithotomy should not be undertaken without first trying what relief can be obtained by the use of the latter ingenious instrument.

I shall next describe the various methods of cutting for the stone, beginning with the most ancient, called the *apparatus minor*, and ending with the modern proposal of employing a knife in preference to a gorget.

OF THE APPARATUS MINOR CUTTING ON THE GRIPE, OR CELSUS'S METHOD.

The most ancient kind of lithotomy was that practised upwards of two thousand years ago by Ammonius, at Alexandria, in the time of Herophilus and Erasistratus, and by Meges at Rome, during the reign of Augustus; and being described by Celsus, is named *Lithotomia Celsiani*. As the stone, fixed by the pressure of the fingers in the anus, was cut directly upon, it has been called *cutting on the gripe*, a knife and a hook being the only instruments used. The appellation of the *less apparatus* was given to it by Marianus in order to distinguish it from a method which he described, called the *apparatus major*, from the many instruments employed.

The operation was done in the following way. The rectum was emptied by a glyster, a few hours previously; and, immediately before cutting, the patient was desired to walk about his chamber, to bring the stone down to the neck of the bladder; he was then placed in the lap of an assistant, or secured in the manner now practised in the lateral operation. The surgeon then introduced the fore and middle fingers of his left hand, well oiled, into the anus; while he pressed with the palm of his right hand on the lower part of the abdomen, above the pubes, in order to promote the descent of the stone. With the fingers the calculus was next griped, pushed forwards towards the neck of the bladder, and made to protrude and form a tumour on the left side of the perinæum. The operator then took a scalpel and made a lunated incision through the skin and cellular substance, directly on the stone near the anus, down to the neck of the bladder, with the horns towards the hip. Then, in the deeper and narrower part of the wound, a second transverse incision was made on the stone into the neck of the bladder itself, till the flowing out of the urine showed that the incision exceeded in some degree the size of the stone. The calculus, being strongly pressed upon with the fingers, next started out of itself, or was extracted with a hook for the purpose.—(*Celsus, lib.* 7, *cap.* 26. *J. Bell's Principles, vol.* 2, *p.* 42. *Allan on Lithotomy, p.* 10.)

The objections to cutting on the gripe are, the impossibility of always dividing the same parts; for those which are cut will vary according to the degree of force employed in making the stone project in the perinæum. When little exertion is made, if the incision be begun just behind the scrotum, the urethra may be altogether detached from the prostate; if the stone be much pushed out, the bladder may be entered beyond the prostate, and both the vesiculæ seminales and vasa deferentia inevitably suffer. Lastly, if the parts are just sufficiently protruded, the neck of the bladder will be cut, through the substance of the prostate gland.—(*Allan on Lithotomy. Burns, in Edinb. Surg. Journal, Nov. XIII. J. Bell, vol.* 2, *p.* 59.)

The preceding dangers were known to Fabricius Hildanus, who attempted to obviate them by cutting on a staff introduced through the urethra into the bladder. He began his incision in the perinæum, about half an inch on the side of the raphe; and he continued the cut, inclining the knife, as he proceeded, towards the hip. He continued to divide the parts till he reached the staff, after which he enlarged the wound to such an extent as permitted him easily with a hook to extract the stone, which he had previously brought into the neck of the bladder by pressure with the fingers in the rectum.—(*Burns.*) In this way Mr. C. Bell has operated with success.—(*J. Bell.*)

The apparatus minor, as practised by Fabricius, with the aid of a staff, is certainly a very simple operation on children, and some judicious surgeons doubt the propriety of its present neglected state. You cut, says an eminent writer, upon the stone, and make of course with perfect security an incision exactly proportioned to its size. There is no difficult nor dangerous dissection; no gorget nor other dangerous instrument thrust into the bladder, with the risk of its passing between that and the rectum; you are performing expressly the lateral incision of Raw and Cheselden, in the most simple and favourable way. The *prisca simplicitas instrumentorum* seems to have been deserted for the sake of inventing more ingenious and complicated operations.—(*J. Bell.*)

Celsus has delivered one memorable precept in his description of lithotomy, *ut plaga paulo major quam calculus sit;* and he seems to have known very well that there was more danger in lacerating than cutting the parts.

The simplicity of the apparatus minor, however, formerly emboldened every quack to undertake it; and as this was followed by the evils and blunders unavoidably originating from ignorance, at the same time that it diminished the emolument of regular practitioners, the operation fell into disrepute.—(See *Heister.*) It was longer practised, however, than all the other methods, having been continued to the commencement of the 16th century; and it was performed at Bordeaux, Paris, and other places in France, on patients of all ages, by Raoux, even as late as 150 years ago. Frère Jaques occasionally had recourse to it; and it was successfully executed by Heister.—(*Part* 2, *chap.* 140.) A modern author recommends it always to be preferred on boys under fourteen.—(*Allan, p.* 12.)

APPARATUS MAJOR.

So named from the multiplicity of instruments employed; or the Marian method, from having been first published by Marianus Sanctus, in 1524, as the invention of his master Johannes de Romanis.

This operation, which came into vogue, as we have noticed, from avaricious causes, was rude and painful in its performance, and very fatal in its consequences. The apology for its introduction was the declaration of Hippocrates, that the *wounds of membranous parts are mortal*. It was contended, however, that such parts might be dilated with impunity; and on this principle of dilatation Romanis invented a complex and dangerous plan of operating; one very incompetent to fulfil the end proposed; one which, though supposed only to dilate, really lacerated the parts.—(*Burns.*)

The operator, kneeling on one knee, made an incision with his razor along the perinæum, on one side of the raphe; and feeling with his little finger for the curve of the staff, he opened the membranous part of the urethra; and fixing the point of the knife in the groove of the staff gave it to an assistant to hold, while

he passed a probe along the knife into the groove of the staff, and thus into the bladder. The urine now flowed out, and the staff was withdrawn. The operator next took two conductors, a sort of strong iron probes; one, named a female conductor, having in it a groove, like one of our common directors: the other, the male conductor, having a probe point corresponding with that groove. The grooved, or female conductor, being introduced along the probe into the bladder, the probe was withdrawn, and the male conductor passed along the groove of the female one into the bladder. Then commenced the operation of dilating. The lithotomist took a conductor in each hand, and by making their shafts diverge, dilated, or, in plain language, tore open the prostate gland.—(*J. Bell.*)

It would be absurd in me to trace the various dilating instruments contrived for the improvement of this barbarous operation, by the Colots, Maréchal, Le Dran, Paré, &c. Among the numerous glaring objections to the apparatus major, we need only notice the cutting of the bulb of the urethra, not sufficiently dividing the membranous part of the urethra, nor the transversalis perinæi muscle, which forms a kind of bar across the place where the stone should be extracted; violent distention of the membranous part of the urethra and neck of the bladder; laceration of these latter parts; large abscesses, extravasation of urine, and gangrene; frequent impotency afterward; and extensive fatality. Bertrandi even saw the urethra and neck of the bladder torn from the prostate by the violence employed in this vile method of operating.—(*Opérations de Chir. p.* 169.) However, Paré, Le Dran, Le Cat, Mery, Morand, Maréchal, Raw, and all the best surgeons in Europe, most strangely practised this rash method for two hundred years, till Frère Jacques, in 1697, taught at Paris the original model of lithotomy, as commonly adopted at the present day.

THE HIGH OPERATION

Was first practised in Paris in 1475, by Colot, as an experiment on a criminal, by permission of Louis the XI.; and the patient recovered in a fortnight. The earliest account of this method of operating was published in 1556, by Pierre Franco, in his *Treatise on Hernia, ed.* 1. He performed it on a child two years old, after finding the calculus too large to admit of being extracted from the perinæum, where he had first made an opening; his remarks, however, tend to discourage the practice. Rossetus recommended it with great zeal in his book entitled *Partus Cæsarius*, printed in 1591; but he never performed the operation himself. Tolet mentions the trial of it in the Hôtel-Dieu, but, without entering into the particular causes of its discontinuance, merely says that it was found inconvenient. About the year 1719, it was first done in England by Mr. Douglas; and after him practised by others.—(*Sharp's Operations.*)

The patient being laid on a square table, with his legs hanging off, and fastened to the sides of it by a ligature passed above the knee, his head and body lifted up a little by pillows, so as to relax the abdominal muscles, and his hands held steady by some assistants; as much barley-water as he could bear, which was often about eight ounces, and sometimes twelve, was injected through a catheter into the bladder.

In order to prevent the reflux of the water, an assistant grasped the penis the moment the catheter was withdrawn, holding it on one side in such a manner as not to stretch the skin of the abdomen; then with a round-edged knife an incision, about four inches long, was made between the recti and pyramidal muscles, through the membrana adiposa, as deep as the bladder, bringing its extremity almost down to the penis; after this, with a crooked knife, the incision was continued into the bladder, and carried a little under the os pubis; and immediately upon the water's flowing out, the forefinger of the left hand was introduced, which directed the forceps to the stone.—(*Sharp's Operations.*) Sabatier disapproves of making the cut in the bladder from below upwards, lest the knife injure the peritoneum.—(*Méd. Opératoire, t.* 3, *p.* 169.)

Although this method of operating appears at first view feasible enough, several objections soon brought it into disuse. 1. The irritation of a stone often causes such a thickened and contracted state of the bladder, that this viscus will not admit of being distended so as to rise above the pubes. 2. If the operator should break the stone, the fragments cannot be easily washed away, but, remaining behind, form a nucleus for a future stone. 3. Experience has proved that the high operation is very commonly followed by extravasation of urine, attended with suppuration and gangrenous mischief in the cellular membrane of the pelvis. This happens because the urine more readily escapes out of the wound in the bladder than through the urethra; and also because, when the bladder contracts and sinks behind the os pubis, the wound in it ceases to be parallel to that in the linea alba and integuments, and becomes deeper and deeper. For the prevention of these ill consequences, says Sabatier, it will be in vain to make the patient lie in a horizontal posture, and keep a catheter introduced, as Rousset and Morand recommended: the bad effects being still neither less frequent nor less fatal.—(See *Médecine Opératoire, t.* 3, *p.* 161, *edit.* 2.) And Sir Everard Home confesses, that while the high operation for the stone had no other channel but the wound for carrying off the urine, it seemed to him a method which ought never to be adopted; "the urine almost always insinuating itself into the cellular membrane behind the pubes, producing sloughs, and consequently abscesses."—(*On Strictures, vol.* 3, *p.* 359, *8vo. Lond.* 1821.) 4. The danger of exciting inflammation of the peritoneum. 5. The injection itself is exceedingly painful, and however slow the fluid be injected, the bladder can seldom be dilated enough to make the operation absolutely secure; and when hastily dilated, its tone may be destroyed.—(See *Sharp, Allan, Sabatier, &c.*)

Some judicious surgeons of the present day are decidedly of opinion, that when a stone in the bladder is known to be very large, no attempt ought ever to be made to extract it from the perinæum. Scarpa declares, that the lateral operation should not be practised when the calculus exceeds twenty lines in its small diameter.—(See *Memoir on the Cutting Gorget of Hawkins, p.* 8, *transl. by Briggs.*) In such cases, it is true, the surgeon may do the lateral operation, and try to break the stone. But ought this proceeding to be preferred to the high operation? I speak particularly of cases in which the stone is known to be of very large dimensions before any operation is begun. Were the lateral operation commenced, the stone, if too large for extraction, must of course be broken; for it is then too late to adopt the high operation with advantage. That such things have been done, however, and yet the patients escaped, is a truth which cannot be denied. Deschamps mentions an instance in which M. Lassus, after using Hawkins's gorget, could not draw out the calculus, and he therefore immediately did the high operation, and the patient recovered. Indeed, the second example of the high operation on record, was done by Franco under similar circumstances, and the patient was saved. I have also heard of a modern French surgeon who began with the lateral operation, but finding a large calculus, ended with performing the high operation, without the least delay or hesitation: the patient died.

Mr. S. Sharp, an excellent practical surgeon in his time, after noticing, with great impartiality, the objections which were then urged against the high operation, says, that he should not be surprised if hereafter it were revived and practised with success; an observation which implied that he foresaw that the method was capable of being so improved as to free it from its most serious inconveniences. In fact since his time, various attempts have been made to introduce the high operation anew, and upon improved principles. Frère Côme, in particular, knew very well that there were circumstances, as, for instance, a calculus above a certain size, disease of the urethra, or prostate gland, &c., where the lateral operation was liable to great difficulties and disadvantages, and where the high operation, if it could be perfected, would be a fitter and safer mode of proceeding. However, it was only in such cases, and not in all, that Frère Côme thought the method better than the lateral operation. He had also discernment enough to perceive that it was extremely desirable to invent some means whereby the painful and hurtful distention of the bladder, for the purpose of making this organ rise behind the pubes, would be rendered unnecessary, at the same time that some measure was adopted for letting the urine have a more depending outlet, than the wound in the hypogastric region. In the early editions of this Dictionary, the

error was committed of representing Côme to have cut the neck of the bladder as well as its fundus; a mistake which I first became aware of upon the perusal of Mr. Carpue's interesting work on lithotomy. The fact is, that Côme did not wound the bladder in two places, but operated after the following way: he first introduced through the urethra into the bladder a staff, which was then held by an assistant. An incision, an inch in length, was now made in the perinæum, in the same direction as in the lateral operation. Another incision was made in the membranous part of the urethra along the groove of the staff, as far as the prostate gland. A very deeply grooved director was then passed along the staff into the bladder, and the latter instrument was withdrawn. By means of the director, a *sonde à dard*, or kind of catheter furnished with a stilette, was now introduced into the bladder, and the director taken out. An incision was then made, about three or four inches in length, just above the symphysis of the pubes, down to, and in the direction of, the linea alba. A trocar, in which there was a concealed bistoury, was next passed into the linea alba, close to the pubes, and the blade of the knife then started from its sheath towards the handle of the instrument, while its other end remained stationary. In this manner the lower part of the linea alba was cut from below upwards, and an aperture was made, which was now enlarged with a probe-pointed curved knife, behind which a finger was kept, so as to push the peritoneum out of the way. Côme then took hold of the *sonde à dard* with his right hand, and elevating its extremity, lifted up the fundus of the bladder, while with the fingers of his left hand he endeavoured to feel its extremity in the wound. As soon as the end of the instrument was perceived, it was taken hold of between the thumb and middle finger, the peritoneum was carefully kept up out of the way, and the stilette was pushed by an assistant from within outwards through the fundus of the bladder. The bladder being thus pierced, the operator introduced into a groove in the stilette a curved bistoury, with which he divided the front of the bladder from above downwards, nearly to its neck. He then passed his fingers into the opening, and keeping up the bladder with them, withdrew the *sonde à dard* altogether. But as it was desirable that both his hands should be free, the bladder was prevented from slipping away by means of a suspensory hook, held by an assistant as soon as the opening was found to be already ample enough, or had been enlarged to the necessary extent. Côme next introduced the forceps, took out the stone, and passed a cannula, or elastic gum catheter, through the wound in the perinæum into the bladder, so as to maintain a ready outlet for the urine, and divert this fluid from the wound in the bladder. In women, of course, the catheter was passed through the meatus urinarius. And I ought here to observe, that Côme, like Scarpa, thought the high operation especially advisable for females, because his experience had taught him, that the division, or dilatation, of the meatus urinarius was generally followed by an incontinence of urine.—(See *Nouvelle Méthode d'extraire la Pierre de la Vessie par dessus le Pubis, &c.* 8vo. *Bruxelles*, 1779.)

Another modification of the high operation was suggested by Deschamps, who, instead of opening the membranous part of the urethra, as Côme did, perforated the bladder from the rectum, and through the cannula of the trocar effected the same objects which the latter lithotomist accomplished by means of the incision in the membranous part of the urethra. Of the two plans, that devised by Côme is unquestionably the best, because not attended with a double wound of the bladder, a thing which, I conceive, must always be highly objectionable.

Dr. Souberbielle, who practises Côme's method, introduces a silver wire through the cannula of the *sonde à dard*, and passes it through the wound made in the linea alba. The wire is then held while the *sonde à dard* is withdrawn, and a flexible gum-catheter is passed by means of the wire into the bladder through the wound in the membranous part of the urethra. The wire is now withdrawn, and the catheter is fixed with tapes, passed round the thighs and pelvis, and a bladder is tied to it for the reception of the urine. "A piece of soft linen, half an inch wide, and six or eight inches long, is to be introduced by means of a pair of forceps into the bottom of the bladder;" the object of which slip of linen is to carry off such urine as may not escape through the catheter. Lint and light dressings are applied, and a bandage round the abdomen. Great care is to be taken to keep the catheter pervious, and, usually on the third day, the slip of linen may be taken out, and the wound closed with adhesive plaster.—(See *Carpue's History of the High Operation*, p. 171, 172.)

Sir Everard Home made trial of Dr. Souberbielle's method in St. George's Hospital, and though some difficulty and delay occurred in the operation, on account of the stone being encysted, the result was successful. Subsequently to this case, however, Sir Everard had invented and practised another method, which, as far as I can judge, is better than that of Côme or Souberbielle, though its principles are the same. When it is considered, that in the operation of these last lithotomists, the neck of the bladder is not opened, and the catheter enters this receptacle through the prostatic portion of the urethra, it must be immediately obvious that the incision in the perinæum cannot answer any material object, because a tube may be placed in the same position by passing it through the urethra from the orifice in the glans. The retainer, or bracelet, invented for keeping the catheter in the bladder in cases of enlargement of the prostate gland, seemed to Sir Everard Home peculiarly applicable to the high operation, since it keeps the tube steadily in the natural canal, and renders the wound in the perinæum unnecessary. Bracelets for this purpose, extremely elastic, and producing no irritation, are sold by Mr. Weiss, of the Strand. They are furnished with small rings, to which the outer end of the catheter is fixed by means of string.

Sir Everard Home performed his new operation for the first time in St. George's Hospital, on the 26th of May, 1820. "An incision was made in the direction of the linea alba, between the pyramidales muscles, beginning at the pubes, and extending four inches in length: it was continued down to the tendon. The linea alba was then pierced close to the pubes, and divided by a probe-pointed bistoury to the extent of three inches. The pyramidales muscles had a portion of their origin at the symphysis pubis detached to make room. When the finger was passed down under the linea alba, the fundus of the bladder was felt covered with loose, fatty, cellular membrane. A silver catheter, open at the end, was now passed along the urethra into the bladder, and when the point was felt by the finger in the wound, pressing up the fundus, a stilet that had been concealed was forced through the coats of the bladder, and followed by the end of the catheter. The stilet was then withdrawn, and the opening through the fundus of the bladder enlarged towards the pubes, by a probe-pointed bistoury, sufficiently to admit two fingers, and then the catheter was withdrawn. The fundus of the bladder was held up by one finger, and the stone examined by the fore-finger of the right hand. A pair of forceps, with a net attached, was passed down into the bladder, and the stone directed into it by the finger: the surface being very rough, the stone struck upon the opening of the forceps, and being retained there by the finger, was extracted. A slip of linen had one end introduced into the bladder, and the other was left hanging out of the wound, the edges of which were brought together by adhesive plaster. A flexible gum catheter, without the stilet, was passed into the bladder by the urethra, and kept there by an elastic retainer surrounding the penis. The patient was put to bed, and laid upon his side, in which position the urine escaped freely through the catheter." As no blood had been lost in the operation, twelve ounces were taken from the arm. The next day the slip of linen was withdrawn, as useless and irritating, the catheter, while pervious, preventing any urine from escaping by the wound. Sir Everard thinks, that in future the linen need only be left in the external wound, so as to prevent collections of matter, and carry off any urine which may issue from the opening in the bladder when the catheter happens to be stopped up. For this operation, Sir Everard particularly recommends catheters, with their insides polished like their outsides, in order that they may better resist the effects of the urine. Suffice it to add, with respect to the above case, that the boy soon recovered, the bladder having resumed its healthy functions in ten days, although the calculus was of the roughest possible kind.

Sir Everard Home repeated his new method on a gentleman, who went out in his carriage with the external wound completely healed, on the 14th day after the operation. The only particulars which need here be noticed, in regard to the latter case, are, that some difficulty was experienced in bringing the point of the catheter forwards towards the pubes, and the slit in the front of the instrument made it so incapable of bearing lateral motion, that the two sides were twisted over one another.—(*On Strictures, vol.* 3, *p.* 359, 8*vo. Lond.* 1820.) Some other cases, however, which have occurred in St. George's Hospital, have had the effect of satisfying numerous very good judges, that, as a general practice, the high operation ought to be abandoned.

Whoever follows this method of operating should always be provided with several tubes and stilets of different lengths and curvatures; for, in the only case in which I have seen the operation attempted, the extremity of the catheter could not be made to project the fundus of the bladder towards the pubes, and after long protracted endeavours had been made to bring the end of the instrument upwards and forwards, the tube broke, and the operation was left unfinished. The impression upon my mind was, that no resistance of the bladder could account for what happened, and that the fault lay in the instrument itself, which should have been exchanged for another of more suitable form, as soon as it was found to be inapplicable. And I believe that if attention be paid to the suggestion of always having at hand a sufficient number of tubes and stilets of different lengths and curvatures, Sir Everard Home's new method will be the best modification of the high operation yet proposed. The slip of linen, however, I think is more likely to do harm by its irritation than any good, as a conductor of the urine or matter out of the wound. At all events, as Sir Everard has observed, it should never be passed into the bladder itself. Whenever I am asked my opinion of the high operation, I always restrict my approval of farther trials of it to cases in which the calculus is known beforehand to be of very large size, or the urethra and prostate gland are diseased. The reasons urged by Mr. Carpue, in favour of the high operation in most cases are: 1. Because it is generally performed in less time; a point which may be disputed, though it is perhaps not worth contesting, since the danger of an operation cannot always be truly estimated by the length of time which the patient remains in the operating room, slow and gentle proceedings sometimes contributing to his safety. 2. There is less pain; a remark, the justness of which must depend, perhaps, upon the manner in which each operation is done. 3. There is no fear of a fatal hemorrhage; a consideration which I admit is one good reason in favour of the high operation; though the lateral operation is only subject to risk of hemorrhage when the incisions are directed in a manner not sanctioned in this Dictionary. 4. There is no division of the prostate and inferior part of the bladder; no, but there is one of the fundus, so that perhaps on this point the two operations stand upon an equality. As for there being no danger in the high operation of wounding the rectum, it is undoubtedly an advantage, though the accident, as far as I have seen, is not followed by any serious consequences, and can only happen from inattention to rules easily followed. 5. The stone, if of a certain size, cannot be extracted by the lateral operation, but admits of being so by the high operation. Of all the reasons for the latter practice, this appears to me the strongest, with the exception, perhaps, of disease in the urethra and prostate. 6. A small stone is more readily discovered in this method than in the lateral operation; a point which I consider questionable, and, at all events, not sufficiently important to form a ground for the high operation. Indeed, the long time which several patients in St. George's Hospital were subjected to the agony caused by repeatedly groping and *fishing* for the stone in vain, has now filled a great many judicious surgeons with strong aversion to a continuance of the attempts to revive in this country the practice of the high operation. 7. If a stone breaks, the particles can be extracted with more certainty than in the lateral operation: on this question authors differ, and the remarks in the foregoing passage are rather against the correctness of the statement. 8. The high operation enables the surgeon to remove encysted calculi with greater ease; a reason which may perhaps be generally true, but which is somewhat weakened by the consideration that encysted calculi are not very frequent. Mr. Carpue allows that the high operation should not be selected when the patient is corpulent, and the bladder is thickened and diseased, so that its fundus cannot be raised above the pubes.—(See *Hist. of the High Operation*, *p.* 173, 8*vo. Lond.* 1819.)

Although Scarpa thinks the lateral operation unlikely to answer when the calculus exceeds twenty lines in its less diameter, he considers the high operation also useless in such a case, and even fatal; because, according to his observations, when the stone is very large, the bladder and kidneys are almost always too much diseased for the patient to recover.—(*Observazioni sul Taglio Retto Vesicale*, *p.* 3 *and* 48, 4*to. Pavia*, 1823.) He has only met with two cases to the contrary. However, in another place, in considering the advantages and disadvantages of the high operation, as compared with that performed through the rectum, in cases where the stone is too large to be extracted by the perinæum, he gives his decided preference to the former.—(*P.* 47.) The high operation he also considers the only method by which women can be cured without leaving them afflicted with an incontinence of urine.—(*P.* 49.) However, after the facts related by Sir A. Cooper, Mr. Thomas and others (*Lond. Med. Chir. Trans.*), and Dr. Hamilton (*Edin. Med. Chir. Trans. vol.* 2, *p.* 117), few surgeons would think of having recourse to so dangerous an operation in preference to the simple and safe plan of dilating the meatus urinarius. I decline entering into any strict consideration of the inconveniences to which this method is exclusively subject, especially the greater vicinity of the wound to the peritoneum and small intestines, and the division of that membrane and protrusion of the viscera: accidents, which will be found by any body who chooses to look over the cases on record, not to have been unfrequent.

In December, 1818, Mr. Kirby, of Dublin, performed the high operation for the extraction of an elastic gum catheter, which had slipped into the bladder through the cannula of a trocar, with which paracentesis had been performed. No contrivance was found necessary for lifting up the fundus of the bladder. The puncture already made was enlarged, and after the operation was finished, a catheter was placed in the wound, but was withdrawn on the 4th day, as the urine passed out by the side of it. The case terminated well.—(See *Kirby's Cases*, *p.* 92, *&c. 8vo. Dublin*, 1819.) In an example, in which the calculus was lodged in the fundus of a little boy's bladder, aged six years, Dr. Ballingall undertook the high operation, in the expectation that the stone might have been more easily extracted above the pubes than from the perinæum. Great difficulties were experienced, however, in getting it out; and the peritoneal inflammation which ensued had a fatal termination. The stone measured more than two inches in one diameter, and one inch and a half in the other; while the space between the tuberosities of the ischium was only two and a half inches.—(See *Edin. Med. Chir. Trans. vol.* 2.) Lithotomy, in whatever way performed, when the stone is encysted (a circumstance that unavoidably lengthens the operation and leads to great disturbance of the parts), is generally unsuccessful; and I do not, therefore, consider this example as more against the high than the lateral operation, which might have been attended, as Dr Ballingall observes, with even greater difficulties.

[The high operation of lithotomy was first performed in this country by Dr. Gibson, Professor of Surgery in the University of Pennsylvania, and since by Dr. M'Clellan and others. It was preferred because of the great size of the stone in these cases, rendering it improbable that extraction could be effected through the perineum.—*Reese.*]

LATERAL OPERATION.

So named from the prostate gland and neck of the bladder being laterally cut.

From some quotations made by Mr. Carpue from the works of Franco, it appears clear enough that the latter was not only the inventor of the lateral operation, but that he placed his patients in the position adopted at the present time, used similar instruments to those now employed (excepting that his gorget had no sharp side), and made the same incisions. Now,

as this claim of Franco to an invention of such importance had been nearly or quite forgotten, when Mr. Carpue's work made its appearance, the latter gentleman deserves much praise for reminding the profession of what is due to the memory of an old surgeon whose name must flourish as long as the history of the rise and progress of surgery is interesting to mankind. But though Franco appears probably to have practised the lateral operation, or something very much like it, he never established the method as a permanent improvement in surgery, which measure was left to be completed long afterward by an ecclesiastic, who called himself Frère Jacques: he came to Paris in 1697, bringing with him abundance of certificates of his dexterity in operating; and having made his history known to the court and magistrates, he got an order to cut at the Hôtel-Dieu and the Charité, where he operated on about fifty persons. His success, however, did not equal his promises, and according to Dionis, some loss of reputation was the consequence.

Frère Jacques used a large round staff without a groove, and when it was introduced into the bladder, he depressed its handle, with an intention of making the portion of this viscus, which he wished to cut, approach the perinæum. He then plunged a long dagger-shaped knife into the left hip, near the tuber ischii, two finger-breadths from the perinæum, and pushing it towards the bladder, opened it in its body, or as near the neck as he could, directing his incision upwards from the anus. He never withdrew his knife till a sufficient opening had been made for the extraction of the stone. Sometimes he used a conductor to guide the forceps, but more commonly directed them with his finger, which he passed into the wound after withdrawing the knife. When he had hold of the stone, he used to draw it out in a quick rough manner, heedless of the bad consequences. His only object was to get the stone extracted, and he disregarded every thing else; all preparatory means, all dressings, all after-treatment.—(*Allan, p.* 23.)

But although Frère Jacques, totally ignorant of anatomy, and rude and indiscriminate in practice, sunk into disrepute, some eminent surgeons conceived, from a consideration of the parts which he cut, that his method might be converted into a most useful operation.

The principal defect in his first manner of cutting was the want of a groove in his staff, and the consequent difficulty of carrying the knife into the bladder. At length Frère Jacques was prevailed upon to study anatomy, by which his judgment was corrected, and he readily embraced several improvements, which were suggested to him. Indeed, we are informed, that he now succeeded better and knew more than is generally imagined. Mr. Sharp says, that when he himself was in France in 1702, he saw a pamphlet published by this celebrated character, in which his method of operating appeared so much improved, that it scarcely differed from later practice. Frère Jacques had learned the necessity of dressing the wound after the operation, and had profited so much from the criticisms of Mery, Fagon, Felix, and Hunauld, that he then used a staff with a groove, and, what is more extraordinary, had cut thirty-eight patients successively, without losing one.—(*Sharp's Operations.*)

In short, as a modern writer has observed, he lost fewer patients than we do at the present day, in operating with a gorget. He is said to have cut nearly 5000 patients in the course of his life, and though persecuted by the regular lithotomists, he was imitated by Maréchal at Paris, Raw in Holland, and by Bamber and Cheselden in England, where his operation was perfected.—(*Allan.*)

For a particular history of Frère Jacques, and his operations, Allan refers us to *Bussiere's Letter to Sir Hans Sloane, Philos. Trans.* 1699. *Observations sur la Manière de Tailler dans les deux Sexes, pour l'Extraction de la Pierre, pratiquée par F. Jacques, par J Mery. Lister's Journey to Paris in* 1698. *Cours d'Opérations de Chirurgie, par Dionis. Garengeut, Traité des Opérations, t.* 3. *Morand, Opuscules de Chirurgie, part* 2.

Among the many who saw Frère Jacques operate, was the famous Raw, who carried his method into Holland, and practised it with amazing success. He never published any account of it himself, though he admitted several to his operations: but after his death, his successor, Albinus, gave the world a very circumstantial detail of all the processes; and mentions, as one of Raw's improvements, that he used to open the bladder between its neck and the ureter. But either Albinus in his relation, or Raw himself in his supposition, was mistaken; since it is almost impossible to cut the bladder in that part upon the common staff, without also wounding the neck.—(*Sharp, in Operations and Critical Inquiry.*)

Raw's method was objectionable even when accomplished, as the urine could not readily escape, and it became extravasated around the rectum so as to produce terrible mischief. There is little doubt that Raw's really successful plan was only imitative of Frère Jacques's second improved one, though he was not honourable enough to confess it.

Dr. Bamber was the first man in England who made a trial of Raw's method on the living subject, which he did in St. Bartholomew's Hospital. Cheselden, who had been in the habit of practising the high operation, gladly abandoned it on receiving the account of Raw's plan and success; and, a few days after Bamber, he began to cut in this way in St. Thomas's Hospital.

Cheselden used at first to operate in the following manner. The patient being placed and tied much in the same way as is done at this day, the operator introduces a hollow grooved steel catheter into the bladder, and with a syringe, mounted with an ox's ureter, injects as much warm water into it as the patient can bear without pain: the water being kept from running out by a slip of flannel tied round the penis, the end of the catheter is to be held by an assistant, whose principal care is to keep it from rising, but not at all to direct the groove to the place where the incision is to be made.

With a pointed convex-edged knife, the operator, beginning about an inch above the anus, on the left side of the raphe, between the accelerator urinæ, and erector penis, makes an incision downwards by the side of the sphincter ani, a little obliquely outwards as it descends, from two and a half to four inches in length, according to the age of the patient, or size and structure of the parts. This incision he endeavours to make all at one stroke, so as to cut through the skin, fat, and all, or part of the levator ani, which lies in his way. This done, he passes his left fore-finger into the middle of the wound, in order to press the rectum to one side, that it may be in less danger of being cut; and taking a crooked knife in his other hand, with the edge on the concave side, he thrusts the point of it through the wound, close by his finger, into the bladder, between the vesicula seminalis and os ischium of the same side. This second incision is continued upwards till the point of the knife comes out at the upper part of the first. The incision being completed, the operator passes his left fore-finger through the wound into the bladder, and having felt and secured the stone, he introduces the forceps, pulls out his finger, and extracts the stone.

As the bladder was distended, Cheselden thought it unnecessary to cut on the groove of the staff, and that as this viscus was sufficiently pressed down by the instrument, the forceps could be very well introduced without the use of any director except the finger. —(*Postscript to Douglas's History of the Lateral Operation*, 1726.)

With respect to this first of Cheselden's plans, Sharp says, the operations were exceeding dexterous; but the wound of the bladder, retiring back when it was empty, did not leave a ready issue for the urine, which insinuated itself among the neighboring muscles and cellular substance, and four out of the ten patients on whom the operation was done, perished, and some of the others narrowly escaped.—(*Sharp's Operations.*)

Cheselden, finding that he lost so many patients in imitating Raw, according to the directions given by Albinus, began a new manner of operating, which he thus describes: "I first make as long an incision as I well can, beginning near the place where the old operation ends, and cutting down between the musculus accelerator urinæ and erector penis, and by the side of the intestinum rectum: I then feel for the staff, and cut upon it the length of the prostate gland straight on to the bladder, holding down the gut all the while with one or two fingers of my left hand."—(*Anatomy of the Human Body, ed.* 1730.)

It deserves remark, that it was Cheselden's second manner of cutting, which was described in the *Opus*

cules de Chirurgie of Morand, who was deputed, and had his expenses defrayed, by the Royal Academy of Sciences in Paris, to come over to England, and learn from Mr. Cheselden himself, his way of operating for the stone: and accordingly we find that most French authors taking their account from Morand, describe Cheselden's second, not his third operation, as that which he invented, and bears his name. But that Mr. Cheselden never resumed his second manner of cutting, may be inferred from his continuing to describe the third only in all the editions of his anatomy published after 1730.—(*See a note by J. Thomson, M.D., annexed to his new edition of Douglas's Appendix. Edinburgh*, 1802.)

The instruments which Cheselden employed in his third and most improved mode of cutting for the stone, were a staff, an incision knife, a gorget, a pair of forceps, and a crooked needle carrying a waxed thread. The patient being placed on a table, his wrists were brought down to the outsides of his ankles, and secured there by proper bandages, his knees having first been bent, and his heels brought back near his buttocks.

Cheselden used then to take a catheter, first dipped in oil, and introduce it into the bladder, where having searched for and discovered the stone, he gave the instrument to one of his colleagues, whom he desired to satisfy himself whether there was a stone or not. The assistant, standing on his right-hand, held the handle of the staff between his fingers and thumb, inclined it a little towards the patient's right thigh, and drew the concave side close up to the os pubis, in order to remove the urethra as far as possible from the rectum.

The groove of the staff being thus turned outwardly and laterally, Cheselden sat down in a low chair, and keeping the skin of the perinæum steady with the thumb and fore-finger of his left hand, he made the first or outward incision through the integuments from above, downwards, beginning on the left side of the raphe, between the scrotum and verge of the anus, almost as high up as where the skin of the perinæum begins to form the bag containing the testicles. Thence he continued the wound obliquely outwards, as low down as the middle of the margin of the anus, at about half an inch distance from it, and consequently beyond the tuberosity of the ischium. He was always careful to make this outward wound as large as he could with safety. Having cut the fat rather deeply, especially near the rectum, he used to put his left fore-finger into the wound, and keep it there till the internal incision was quite finished; first to direct the point of his knife into the groove of the staff, which he now felt with the end of his finger; and secondly, to hold and prevent the rectum from being wounded, by the side of which his knife was to pass. This inward incision Cheselden made with more caution than the former. His knife first entered the groove of the rostrated or straight part of the staff, through the side of the bladder, immediately above the prostate, and its point was afterward brought along the same groove in the direction downwards and forwards, or towards himself. Cheselden thus divided that part of the sphincter of the bladder which lay upon the prostate gland, of which he next cut the outside of one-half obliquely, according to the direction and whole length of the urethra within it, and finished the internal incision, by dividing the membranous portion of the urethra, on the convex part of his staff.

A sufficient opening being made, Cheselden used to rise from his chair, his finger still remaining in the wound. Next he put the beak of his gorget in the groove of the staff, and then thrust it into the bladder. The staff was now withdrawn, and, while he held the gorget with his left hand, he introduced the forceps with the flat side uppermost, with great caution, along the concavity of the gorget. When the forceps were in the bladder, he withdrew the gorget, and taking hold of the two handles of the forceps with both his hands, he searched gently for the stone, while the blades were still kept shut. As soon as the calculus was felt, the forceps were opened, and an attempt made to get the lower blade under the stone, in order that it might be more conveniently laid hold of. This being done, the stone was extracted with a very slow motion, in order to give the parts time to dilate, and the forceps were gently turned in all directions.

When the stone was very small and did not lie well in the forceps, Cheselden used to withdraw this instrument, and introduce his finger into the bladder, for the purpose of turning the stone, and disengaging it from the folds of the lining of the bladder, in which it was sometimes entangled. Then the gorget was passed in again on the upper side of his finger, and turned as soon as the latter was pulled out. Lastly, the forceps were introduced and the stone extracted. With the view of hindering a soft stone from breaking during its extraction, Cheselden used to put one or more of his fingers between the branches of his forceps, so as to prevent any greater pressure upon it, than what was just necessary to hold it together. But when it did break, or there were more calculi than one, he used to extract the single stones or fragments one after another, repeating the introduction of his fingers and forceps as often as there was occasion. Cheselden took care not to thrust the forceps so far into the bladder as to bruise or wound its opposite side; and he was equally careful not to pinch any folds of its inner coat. In this way Cheselden saved fifty patients out of fifty-two, whom he cut successively in St. Thomas's Hospital.—(*Appendix to the History of the Lateral Operation, by J. Douglas.* 1731.)

Cheselden, with all the enthusiasm of an inventor, believed that he had discovered an operation which was not susceptible of improvement; yet he himself changed the manner of his incision not less than three times, in the course of a few years. 1st. He cut into the body of the bladder, behind the prostate, when he imitated Raw. 2dly. He cut another part of the bladder, viz., the neck, and the thick substance of the prostate; this is his lateral mode of incision. 3dly. He changed a third time, not the essential form of the incision, but the direction in which he moved the knife; for, in his first operation, when imitating the supposed operation of Raw and Frére Jacques, he passed his knife into the body of the bladder, between the tuber ischii and the vesiculæ seminales, and all his incision lay behind the prostate gland. In this second operation, he pushed his knife into the membranous part of the urethra, immediately behind the bulb, and ran it down through the substance of the gland; but his incision stopped at the membranous part or body of the bladder. But in his third operation, after very large external incisions, he passed his knife deeply into the great hollow under the tuber ischii, entered it into the body of the bladder immediately behind the gland, and, drawing it towards himself, cut through the whole substance of the gland, and even a part of the urethra, "cutting the same parts the contrary way." By carrying the fore-finger of the left hand before the knife, in dissecting towards the body of the bladder, he protected the rectum more perfectly than he could do in running the knife backwards along the groove of the staff; and by striking his knife into the body of the bladder, and drawing it towards him through the whole thickness of the gland, he was sure to make an ample wound.—(*J. Bell's Principles of Surgery, vol. 2, part 1, p.* 152.) And, as Mr. Key has correctly stated, Cheselden's aim was to to divide the prostate, in the depending part of its left lobe: the edge of the knife was turned upwards, and in this position carried into the neck of the bladder behind the prostate gland.—(*On the Section of the Prostate Gland, &c. p.* 10.)

LATERAL OPERATION AS PERFORMED AT THE PRESENT DAY WITH CUTTING GORGETS.

The gorget has the same kind of form as one of the instruments used by F. Colot and others, in the performance of the apparatus major, and the common opinion that the conductor of Buldanus was the first model of it, is not exactly true; but it differs from the instruments employed by these ancient surgeons, in having a cutting edge. Sir Cæsar Hawkins thought, that if its right side were sharpened into a cutting edge, it might be safely pushed into the bladder, guided by the staff, so as to make the true lateral incision in the left side of the prostate gland more easily, and with less risk of injuring the adjacent parts, than Cheselden could do with the knife; and surgeons were pleased with a contrivance, which saved them from the responsibility of dissecting parts, with the anatomy of which all were not equally well acquainted.—(*J. Bell, Allan.*)

As Scarpa observes: To render the execution of the lateral operation easier to surgeons of less experience than Cheselden, was the motive which induced Hawkins to propose his gorget. He thought, that two

great advantages would be gained by the use of this instrument; one, of executing invariably the lateral incision of Cheselden; the other, of constantly guarding the patient, through the whole course of the operation, from injury of the rectum, and of the arteria pudica profunda. The utility of the latter object (says Scarpa) cannot be disputed, as it is evident that *the convexity of the director of the instrument defends the rectum from injury*, and that *its cutting edge not being inclined horizontally towards the tuberosity and ramus of the ischium, but turned upwards in the direction of the longitudinal axis of the neck of the urethra, cannot wound the pudic artery.* But with respect to the first advantage, or that of executing precisely the lateral incision of Cheselden, it must be admitted that it does not completely fulfil the intention which he proposed, not only on account of the cutting edge of his instrument not being raised enough above the level of the staff, to penetrate sufficiently the substance of the prostate gland, and consequently to divide it to a proper depth; but because, being too much turned upwards at that part of it which is to lay open the base of the prostate gland, it does not divide it laterally, but rather at its upper part, towards the summit of the ramus of the ischium, and the arch of the pubes; an opening of all others in the perinæum the most confined, and presenting the greatest impediment to the passage of the stone from the bladder.—(See also *Key on Lithotomy*, *p.* 10.) The breadth of the point of the director is, besides, so disproportionate to the diameter of the membranous part of the urethra, that, from the great resistance with which it meets, the instrument may easily slip from the groove of the staff, and pass between the bladder and rectum, *a serious accident, which has very often happened even in the hands of experienced surgeons.*

Scarpa considers all the modifications of Hawkins's gorget proposed by B. Bell, Desault, Cline, and Cruikshank as deteriorations of the original instrument. B. Bell (he observes) has diminished the breadth of the director, but given the cutting edge a horizontal direction. The horizontal direction of the cutting edge is also preferred by Desault, Cline, and Cruikshank; but they have enlarged the director and flattened the part which was previously concave. Aware of the danger of wounding the pudic artery by the horizontal direction of the gorget, they direct the handle of the staff to be inclined towards the patient's right groin, and the gorget to be pushed along it, inclined in such a manner that its obtuse edge may be directed towards the rectum, and its cutting edge placed at a sufficient distance from the tuberosity and ramus of the ischium to avoid wounding the artery. Scarpa contends, however, that it is difficult to give a proper degree of obliquity to the staff, and that such inclination of the instrument must be incommodious, arbitrary, and unstable, in comparison with that position of it in which the handle of the staff is held in a line perpendicular to the body of the patient, and its concavity placed against the arch of the pubes; on which stability of the instrument (says Scarpa) the safety and precision of the lateral operation depend. According to this eminent professor, the defects of Hawkins's original gorget arise from the excessive breadth of the director, particularly at the point; the want of sufficient elevation of the cutting edge above the level of the groove of the staff, and the uncertain inclination of the edge to the axis of the urethra and prostate gland. The cervix of the urethra in a man between thirty and forty years of age is only three lines in diameter at the apex of the prostate gland, four lines in its centre, and five near the orifice of the bladder. The apex of the prostate gland is rather more than two lines in thickness, the body or centre four, and the base six and sometimes eight, which surrounds the orifice of the bladder. In an adult of middle stature, from eighteen to twenty years of age, the thickness of the base of the prostate gland is about two lines less, compared with that of a man of forty, and of a large size. The precise line in which the lateral incision of the prostate gland should be made in an adult (says Scarpa), is found to be inclined to the longitudinal axis of the cervix of the urethra, and of the gland itself, at an angle of 69°. Now, from these data, drawn from the structure of the parts, Scarpa makes the director of his gorget only four lines broad and two deep; the breadth decreasing at the beak. The cutting edge of the instrument is straight near its point, but gradually rises, and becomes convex above the level of the staff, so that its greatest convexity is seven lines broad. Lastly, the inclination of the cutting edge to the longitudinal axis of the director is exactly at an angle of 69°; that is to say, the same as the left side of the prostate gland to the longitudinal axis of the neck of the urethra.—(See *Scarpa's Memoir on Hawkins's Gorget; transl. by Mr. Briggs*, *p.* 12. 17.)

For more than twenty years the instrument makers in London have been in the habit of selling a gorget, which Mr. Abernethy invented, and which, in the particularity of its cutting edge turning up at an angle of 45°, bears much analogy to the instrument lately recommended by Scarpa. The cutting edge is straight, and that useless and dangerous part of a gorget, sometimes called the shoulder, is removed. Admitting that the principles of the lateral operation, as inculcated by Scarpa, are correct, and of which I shall presently speak, it appears to me that Mr. Abernethy's gorget is far preferable to that very recently proposed by Scarpa. Its edge is not so immoderately turned up, and it will enter with more ease, and less risk of slipping from the staff, because it has not any projecting shoulder, which, while the staff is firmly held with the beak of the gorget in it, can have no other effect but that of obstructing the passage of the last instrument.

Gorgets which cut on both sides have also been sometimes employed in England, and as a larger opening can be obtained by them, even without trespassing the limits of the incision fixed by Scarpa, that is to say, without cutting any part of the body of the bladder, they appear to promise utility, especially when the stone is suspected to be large. However, they are less used now than they were some years ago, when Sir Astley Cooper employed them in Guy's Hospital; but I am unacquainted with the particular reasons of this change.

[In the United States, when the gorget is used, that of Dr. Physick is preferred, it being capable of receiving a much keener edge near the point. Dr. Gibson has improved the gorget of Dr. Physick, by constructing the blade so as to taper from the outer corner of the cutting edge to the handle of the instrument. Professor Stevens, in his note on Cooper's *First Lines*, *p.* 508, *vol.* 2, says, "It has been urged that the blades are too broad, and that they endanger the cutting of what has been called the prostate fascia, or the partition between the pelvis and the abdomen. Such fears can only arise from mistaken ideas of the anatomy of the parts."—(See *Vol.* 6 *of the Medical Repository.*)—*Reese.*]

Some criticisms on Scarpa's method of operating, and a few remarks on the size and direction of the lateral incision, will be found in a subsequent section of the present article.

Sir A. Cooper, as I think with considerable reason, recommends putting the patient on vegetable diet for a little while previously to the operation. He disapproves of operating when the kidneys are diseased, the bladder is ulcerated, and disease in the chest, asthma, or any irregularity of the circulation prevails. He has found the operation generally more successful in the poor and labouring classes, than in the rich and luxurious. Old age is not considered by him as an objection to the operation, which he even believes most successful in persons from sixty-one to sixty-three years of age. If the patient is loaded with fat, he says, the chance of peritoneal inflammation is always great. According to his experience, convulsions, having a fatal result, are frequent after operations on children, particularly when much blood has been lost.—(See *Lancet*, *vol.* 2, *p.* 316, *&c.*) When a stone of considerable magnitude is accompanied with an enlarged prostate gland, the patient (he says) rarely recovers from the operation. —(*Vol. cit. p.* 345.)

As inflammation of the bladder and peritoneum is the principal danger of this operation, and, under an equal degree of injury and violence, is most likely to happen in a plethoric subject, it has been a question whether venesection should not be practised a day or two before the patient is operated upon, supposing that his age and weakness form no prohibition. The chief reason which prevents the common observance of this practice is, that a great deal of blood is sometimes lost in the operation itself. A vegetable diet for a week or two before the operation seems to be a better plan.

When, however, the loss of blood in the operation has been inconsiderable, the patient is young and strong, and particularly when the operation has been tedious, and the bladder has suffered a good deal, I am disposed to think very favourably of the rule of bleeding the patient as soon as he is put to bed, and recovered from the first depressing effects of the operation. An opening medicine should be given the day before the patient is cut, and a clyster injected a couple of hours before the time fixed upon for the operation, in order to empty the rectum, and thus diminish the chance of its being wounded.

It is generally considered advantageous to let the bladder be somewhat distended, and the patient is therefore directed to retain his urine a certain time before he is cut. Formerly, a jugum penis was sometimes used for confining the urine in the bladder; but since my entrance into the profession, I have never heard of this contrivance being employed. The presence of urine in the bladder, it is conceived, may lessen the chance of the fundus of that organ being injured by the gorget; but as the beak of this instrument should always be in the groove of the staff, I am not sure that the reason for the practice is good. The plan is disapproved of by Sir A. Cooper, who says, that when the urine collected gushes out, the bladder contracts, and embraces the stone so closely that it is difficult to get hold of the foreign body with the forceps.—(See *Lancet*, *vol.* 2, *p.* 347.)

Before the operation, the following instruments should all be arranged ready on a table: a staff of as large a diameter as will easily admit of introduction, and the groove of which is very deep, and closed at the extremity. A sharp gorget, with a beak nicely and accurately adapted to the deep groove of the preceding instrument, so as to glide easily and securely. A large scalpel for making the first incisions. Forceps of various sizes and forms for extracting the stone. A blunt-pointed curved bistoury for enlarging the wound in the prostate, if the incision of the gorget be not sufficiently large, as the parts should never be lacerated. A pair of Le Cat's forceps with teeth for breaking the stone if too large to come through any wound reasonably dilated. A syringe for washing out clots of blood or particles of the stone: a practice, however, not considered necessary by Sir A. Cooper (*Lancet*, *vol.* 2, *p.* 347); a scoop for the removal of small calculi or fragments. Two strong garters or bands, with which the patient's hands and feet are tied together.

The curvature of the staff is a matter of considerable importance; because the direction of the incision through the prostate gland and neck of the bladder is partly determined by it. The French surgeons, convinced of the advantage of introducing the gorget in the direction of the axis of the bladder, always use a staff, which is much more curved than what English surgeons employ.—(See *Roux*, *Voyage fait à Londres en* 1814, *ou Parallèle de la Chir. Anglaise*, *&c. p.* 319.) But I am inclined to believe with Scarpa, that upon the whole it is best to let the curvature of the staff correspond exactly to that of the axis of the neck of the urethra and prostate gland.—(*Opusculi di Chirurgia*, *vol.* 1, *p.* 39.)

After introducing the staff, and feeling that the stone is certainly in the bladder, the patient is to be secured in the same position as was described in the account of Cheselden's latest method of operating.

The assistant, holding up the scrotum with his left hand, is with his right to hold the staff, inclining its handle towards the right groin, so as to make the grooved convexity of the instrument turn towards the left side of the perinæum. Some operators also like the assistant to depress the handle of the staff towards the patient's abdomen, in order to make its convexity project in the perinæum, while others condemn this plan, asserting, that it withdraws the instrument from the bladder.—(*Allan*, *&c.*)

Scarpa disapproves of inclining the handle of the staff towards the patient's right groin, and he expressly recommends this instrument to be held firmly against the arch of the pubes, in a line perpendicular to the body of the patient, so that the convex part of the director may be placed towards the rectum, and take the exact course of the axis of the neck of the urethra and prostate gland.—(*Opusculi*, *&c. p.* 40.) This position of the staff is the firmest and most commodious to the surgeon, and Scarpa maintains, that on such stability of the instrument the safety and precision of the lateral operation depend.

Sir A. Cooper directs the operator to hold the staff perpendicularly, and to let it rest on the stone, as he has seen many instances in which the gorget has not entered the bladder, owing to the staff not having itself passed into it, but rested against the prostate gland.—(See *Lancet*, *vol.* 2, *p.* 319.)

The first incision should always commence below the bulb of the urethra, over the membranous part of this canal, at the place where the operator means to make his first cut into the groove of the staff, and the cut should extend at least three inches, obliquely downwards to the left of the raphe of the perinæum, at an equal distance from the tuberosity of the ischium and the anus. The first cut should descend rather beyond the level of the centre of the anus; for it is a general rule in surgery to make free external incisions, by which the surgeon is enabled to conduct the remaining steps of his operation with greater facility, and nowhere is it so necessary as where a stone is to be extracted.—(*Allan.*) That excellent surgical writer, Callisen, lays it down as a rule to be observed in the lateral operation, *that the incision ought not to extend to such parts as can make no impediment to the extraction of the stone; and, therefore* (says he), *the bulb, and that part of the urethra which is surrounded by the corpus spongiosum, should never be cut.* Only those parts ought to be divided, which firmly resist the safe introduction of instruments into the bladder, and the extraction of the stone. Hence, the integuments must be opened by an ample incision, and the membranous part of the urethra, transversus perinæi muscle, levator ani, and prostate gland be properly divided.—(*Systema Chirurgiæ Hodiernæ*, *pars* 2, *p.* 655.) Like Scarpa, however, he is fearful of making a free cut through the neck of the bladder, and, in lieu of doing so, prefers a slow and cautious dilatation of the parts. When the external cut through the integuments, fat, and accelerator urinæ muscle has been executed, the next object is to divide the transversus perinæi muscle, which stands, like a bar, across the triangular hollow, out of which alone the stone can be easily extracted. A part of the membranous portion of the urethra, adjoining the prostate gland, is next to be laid open; but an extensive cut through it, as far forwards as the bulb, is quite unnecessary, because it will not at all facilitate the passage of the stone outwards.

Having placed the beak of the gorget in the groove of the staff, the operator takes hold of the latter instrument firmly with his left hand, raises its handle from the abdomen, so that it may form nearly a right angle with the body, and stands up. Before attempting to push the gorget into the bladder, however, he should slide it backwards and forwards, with a wriggling motion, that he may first be sure of its beak being in the groove of the staff. The bringing forwards of the handle of the latter instrument, so as to elevate its point, before introducing the gorget into the bladder is also considered of great importance; for it is by this means that the gorget is introduced along the groove of the staff in the axis of the bladder, the only direction unattended with risk of wounding the rectum. In fact, the gorget should be introduced nearly in a direction corresponding to a line drawn from the os coccygis to the umbilicus. It is obvious, however, that the degree in which the handle of the staff should be depressed must depend very much upon the curvature of the instrument.

The utmost attention to the rule last noticed is especially necessary, when a staff with a groove not closed at the end is employed. The neglect of it in this case might make the operator cut the bladder with the gorget in several places, as, according to Mr. B. Bell, has actually happened. But since the gorget, when introduced as nearly as possible in the axis of the bladder, may transfix and otherwise injure this organ, if introduced either too far, or at all beyond the extremity of the staff, I am decidedly of opinion, that every surgeon, who chooses to perform the lateral operation with a gorget, should employ a staff, the groove of which is closed at the extremity, as is invariably done in France, and is expressly enjoined by Professor Scarpa.—(See *Sabatier's Médecine Opératoire*, *t.* 3, *p.* 233, *edit* 2; *and Scarpa's Opusculi di Chirurgia*, *vol.* 1, *p.* 39.) There can also be no doubt of the prudence of endeavouring to have only a fixed and limited length of the

staff in the bladder. Scarpa specifies an inch and a half as the proper distance to which the end of the staff should enter the bladder. However, as it is known that this distinguished professor is an advocate for a very limited incision, and that consequently he would not require the staff to extend farther than an inch and a half into the bladder, I infer, that operators who prefer making a freer opening must use a staff that reaches into this viscus rather farther. Much, however, will depend upon the kind of gorget employed, particularly its breadth, and, if it is to rest against the stone, as advised by Sir A. Cooper, but which method I do not recommend; of course the extent to which it passes, will be determined by the situation of the calculus.

As soon as the gorget is introduced, the staff is to be withdrawn. Some operators next pass the forceps along the concave surface of the gorget, into the bladder: while others recommend the cutting gorget to be withdrawn immediately it has completed the wound; for then the bladder contracts, and its fungus is liable to be cut. The gorget should be withdrawn in the same line in which it is entered, pressing it towards the right side, in order to prevent its making a second wound. If, however, the operator should prefer passing the forceps into the bladder, along the gorget, the latter instrument must be kept quite motionless, lest its sharp edge do mischief; and, at all events, as soon as the forceps is in the bladder, the cutting gorget is to be withdrawn.

Some operators withdraw the cutting gorget, and introduce a blunt one for the guidance of the forceps; a step certainly unnecessary, as the latter instrument will easily pass, when the incision into the bladder is ample and direct, as it ought always to be.

[Professor Stevens, of the University of New-York, always withdraws both the sound and the gorget immediately after making the incision with the latter, and has never found any difficulty in introducing the forceps without any other guide than the fore-finger of the left hand. The point of the forceps he directs to be inclined a little upwards to avoid a little pouch formed by the receding of the loose cellular membrane between the prostate and the rectum.—*Reese.*]

The operator has next to grasp the stone with the blades of the forceps: for which purpose he is not to expand the instrument as soon as it has arrived in the bladder; but he should first make use of the instrument as a kind of probe, for ascertaining the exact situation of the stone. If this body should be lodged at the lower part of the bladder, just behind its neck, the operator is to open the forceps immediately over the stone, and after depressing the blades a little, to gently to shut them so as to grasp it. Certainly, it is much more scientific to use the forceps at first, merely for ascertaining the position of the stone; for when this is known, the surgeon is much more able to grasp the extraneous body in a skilful manner, than if he were to open the blades of the instrument immediately, without knowing where they ought next to be placed, or when shut. No man of experience can doubt, that the injury which the bladder frequently suffers from rough, reiterated awkward movements of the forceps, is not an uncommon cause of such inflammation of this viscus, as extends to the peritoneum, and occasions death.

If the surgeon cannot readily take hold of the stone with the forceps, he should introduce his fore-finger into the rectum and raise up the extraneous body, when it may generally be easily grasped. The stone should be held with sufficient firmness to keep it from slipping away from the blades, but not so forcibly as to incur the risk of its breaking.

[Dr. J. Rhea Barton, of Philadelphia, has invented a forceps for extracting the calculus from the bladder, which is a valuable improvement. Each blade has an oval hole in it, resembling the forceps employed in parturition, so that when the surgeon grasps the stone, it becomes immoveably fixed by entering into the vacuities in the blades. The size of the calculus is therefore not increased by this instrument, and it is effectually prevented from slipping.—*Reese.*]

Sometimes the extraction of the stone is attended with difficulty, owing to the operator having chanced to grasp it in a transverse position, in which circumstance, it is better to try to change its direction, or let it go altogether, and take hold of it in another manner. When the stone is so large that it cannot be extracted from the wound without violence and laceration, the surgeon may either break the stone by means of a strong pair of forceps, with teeth constructed for the purpose; or he may enlarge the wound with a probe-pointed crooked bistoury, introduced under the guidance of the fore-finger of the left hand. The latter plan is generally the best of the two; for breaking the stone always creates serious danger of calculous fragments remaining behind.

However, as nothing can justify the exertion of force in pulling out a stone, if the operator should be afraid of making the wound more ample (it being already large and direct), he must break the stone as above described. As many of the fragments are then to be extracted with the common lithotomy forceps, as can be taken away in this method, after which the surgeon should introduce his finger, in order to feel whether any pieces of the stone still remain behind. Perhaps some of these may be most conveniently taken out with the scoop; but if they are very small, it is best to inject lukewarm water with moderate force into the wound, for the purpose of washing them out.

[Dr. Jameson has invented a forceps for breaking calculi when too large to be extracted through the incision, which will greatly facilitate this process. This instrument is very accurately described in the 8th volume of the American Medical Recorder. No surgeon should be without it, as the necessity for the high operation is thus annihilated, and this forceps would succeed when the calculus is too large to be extracted above the pubis, as is sometimes the case.—*Reese.*]

The surgeon, however, cannot be too strongly impressed with the absolute necessity of using the greatest care not to remove the patient from the operating table while any calculus or fragment remains in the bladder. For the distressing pain of the disorder has been known to recur upon the healing of the wound, and a second operation become necessary. It is a melancholy truth, however, that a fresh calculus may form again in the short space of a few months. I have seen several patients who have been cut for the stone more than once; and Richerand mentions the case of a surgical instrument-maker, resident at the gate of La Charité, in Paris, who has undergone the operation three times in the course of a year and a half, although, after each operation, several eminent surgeons carefully examined the bladder, and could not detect a calculus.—(See *Nosogr. Chir. t.* 3, *p.* 549, *ed.* 4.)

The stone should always be attentively examined immediately it is extracted; because its appearance conveys some information, though not positive, concerning the existence of others. If the stone is smooth on one surface, the smoothness is generally found to arise from the friction of other stones still in the bladder; but when it is uniformly rough, it is a presumptive sign that there is no other one remaining behind. In every instance, however, the surgeon should gently examine the cavity of the bladder with his fore finger; for it would be an inexcusable neglect to put the patient to bed with another stone in his bladder.

After the operation, a simple pledget is commonly laid on the wound, supported by a T bandage; the patient is la'd in bed on his back, with his thighs closed; a piece of oil-cloth and some folded napkins should be laid under him for the reception of the urine, and an opiate administered. However, with respect to the application of a pledget and bandage, and keeping the thighs closed, I confess that my own ideas lead me to regard them as Sir A. Cooper and many other excellent surgeons do, as rather disadvantageous: indeed, I believe the best plan is to leave the wound quite open, so that the urine may have a free outlet, strict attention being paid to keeping the parts clean.

An occasional embarrassment to lithotomists is the circumstance of stones in the bladder not being always free and detached; some are tightly embraced by its coats; others are partially engaged in the ureters; they are sometimes fixed in the neck of the bladder; and are not unfrequently found lodged in sacculi accidentally formed. These cysts are of different sizes: some are small, and exist in a considerable number; some are deeper, with an orifice smaller than their base. They appear to be formed by a prolongation of the internal coat of the bladder. Other sacculi are occasionally found, which seem to be composed of all

the tunics of the bladder, and they are sometimes of such magnitude, that the bladder appears as if it were divided into two or more cavities of nearly equal size. Stones found in these sacculi sometimes present depressions and irregularities, in which fungi of the bladder have been received. When this happens, a portion of such fungous productions is often extracted with the stone; a circumstance that has deceived some practitioners, and led them to suppose that the calculi actually adhered to the coat of the bladder.—(See *Desault's Paris Chirurgical Journ. vol.* 2, *p.* 386, 387.)

The extraction of encysted stones requires different modes of proceeding from those which have been related. Littre conceived, that they might be removed in two ways. When they made only an inconsiderable projection into the bladder, he recommended the introduction of a probe, with which the membrane covering the calculus was to be rubbed, a finger being put into the rectum, in order to keep it down, and facilitate the action of the probe in opening the cyst. When the calculi were very prominent, Littre recommended taking hold of them with a pair of forceps, and contusing and breaking the membranous pouch, with the points and asperities upon the inside of the blades of the instrument. He conceived that suppuration would then destroy the internal parietes of the cyst, and that the stone would fall into the bladder, and admit of being easily extracted. As Sabatier observes, it is plain that this theory, which is founded on the idea entertained by Littre of the manner in which stones become encysted, is totally inadmissible in practice.

Garengeot ventured to pass a bistoury into the bladder for the purpose of disengaging a calculus lodged in a particular cyst at the fundus of this organ, behind the pubes. The knife had some tape twisted round the greatest part of its length, and was introduced under the guidance of the left index finger, which was passed in as far as it could reach. The patient was not more than ten or eleven years old, and consequently of a size which favoured the operation. The stone was loosened and taken out, and the child recovered. However, as Sabatier remarks, there are many instances in which this mode of proceeding cannot be imitated; for, if the calculus should be in a sort of cul-de-sac, as often happens, the entrance of which is narrower than its bottom, and the stone be of considerable size, the incision cannot be made large enough, without risk of cutting through the whole thickness of the bladder, and producing certain death by the effusion of urine in the abdomen.

Other practitioners fancied that the calculus might be taken hold of with the forceps, and turned about in different directions so as to lacerate its connexions, or even that it might be forcibly extracted, without any serious ill consequences. Houstet mentions (see *Mém. de l'Acad. de Chir. t.* 2, *p.* 307, *&c. edit.* 12*mo.*), that Peyronie adopted this method on a patient, thirty-one years of age. The calculus did not resist long, and its surface was found covered with fleshy substances, which formed the adhesions to the bladder. The operation was painful, followed by considerable hemorrhage, tension of the belly, hiccough, cold extremities, and death.

There are some examples, however, in which this bold practice had better success. In 1730, Le Dran extracted from a woman an enormous stone, adherent to that part of the bladder which lies upon the rectum. The irritation of the inequalities of the stone had produced ulceration of the bladder, and fungous growths, which insinuated themselves into the substance of the extraneous body. The adhesions readily yielded, and the excrescences came away with the calculus. Ten days afterward, some thick membranous sloughs were voided. This calculus is engraved in Le Dran's Treatise on the Operations.

Le Dran afterward extracted similar stones, which adhered by a less extensive surface; and he relates an operation done by Maréchal, who, in 1715, extracted, with a pair of forceps, a stone shaped like a calabash, and having its narrow part surrounded by a fungus. In one case, the position of the calculus led Le Dran to suspect that it was fixed in the extremity of the ureter; he shook it occasionally with a pair of forceps; and, lastly, it fell into the bladder, whence it was extracted without difficulty. It resembled a cucumber in shape, and its large extremity had been lodged in the ureter, from which it could only be gradually removed.

Sabatier believes that a case of this description, which must be very uncommon, is the only one in which there is any prospect of removing an encysted stone with success. In other examples, he conceives that it is more prudent to leave the stone and let the wound heal, than expose the patient to an almost certain death by repeated attempts to extract it.—(*Médecine Opératoire, t.* 3, *p.* 190. 194, *ed.* 2.) Desault employed a sort of concealed knife, called a *coupe-bride*, for opening the cavity or cyst; and he has recorded one example, in which he thus successfully extracted from a woman, aged sixty-two, a stone lodged at the insertion of the ureter into the bladder. The bistoury, used by Garengeot, Desault did not consider a safe instrument, as the stones are round, and the knife may slip and pierce the bladder; an objection to which he says the *coupe-bride* is not liable. No injury can be received from its point, as the blade is concealed, nor can any part be divided except what the surgeon intends. If the incision should not be completed at first, the blade may be withdrawn, the semicircular notch of the instrument pushed more forwards, and the incision prosecuted to any extent. This instrument was invented for the express purpose of dividing membranous bands in the rectum; but it was afterward employed with the greatest success for the excision of diseased tonsils, and fungous tumours situated in cavities. The blade is so contrived that when it passes through the semicircular notch, it firmly fixes the parts which are to be divided: a thing that cannot be done either with the scissors or bistoury, as the moveable parts recede, and render the section difficult.—(See *Parisian Chirurgical Journal, vol.* 1, *p.* 33, *&c.*)

Sir A. Cooper mentions, that when the stone is partly in the cyst and partly in the bladder, it may sometimes be removed without opening the latter organ. In the case of a child, he passed his finger into the rectum, and felt the stone, confined in a bag above it. On raising the calculus, it struck firmly against the sound. While the finger was in the rectum, the knife was carried through the perinæum above the bowel, the cyst opened, and the stone taken out, without any farther opening of the bladder itself.—(See *Lancet, vol.* 2, *p.* 346.)

A stone perfectly encysted would not be expected to produce symptoms equal in severity to those which arise from an extraneous body actually in the cavity of the bladder, and generally they do not have this effect; yet, in Houstet's interesting dissertation, several cases are recorded, which prove that encysted stones do sometimes cause the same distressing symptoms which proceed from the presence of a loose calculus in the bladder. Hence, the patients were sounded, and in consequence of the sacs or pouches in which the stones lay not being entirely closed, the calculi were distinctly struck by the instrument, and lithotomy attempted. It deserves particular remark, also, that in a large proportion of these cases, the pouches or cysts were not single, but numerous, occupying different parts of the bladder. In some dissections, referred to by Houstet, cysts of this kind were found not containing any stones whatever; a circumstance that would rather lead one to suspect that, in general, the formation of these sacs precedes that of the calculi commonly found in them.—(See *Obs. sur les Pierres Encystées et Adhérentes à la Vessie par M. Houstet, in Mém. de l'Acad. de Chir. t.* 2, *p.* 268, *ed. in* 12*mo.*)

OF SOME PARTICULAR METHODS AND INSTRUMENTS.

M. Foubert, an eminent surgeon at Paris, devised and practised a plan of his own, which, however, has not been considered by others as worthy of being imitated. The patient having retained his urine, so as to distend his bladder, an assistant, with a convenient bolster, presses the abdomen a little below the navel, in such a manner, that by pushing the bladder forwards, he may make that part of it protuberant which lies between the neck and the ureter. The operator, at the same time, introduces the fore-finger of his left hand up the rectum, and drawing it down towards the right buttock, pushes in a trocar on the left side of the perinæum, near the great tuberosity of the ischium, and about an inch above the anus. Then the trocar is to be carried on parallel to the rectum, exactly between the erector penis and accelerator urinæ muscles, so as to enter the bladder on one side of its neck. As soon as the bladder is wounded, the operator withdraws his fore-finger from the anus.

In the upper part of the cannula of the trocar, there is a groove, the use of which is to allow some urine to escape, immediately the instrument enters the bladder, so that the trocar may not be pushed in any farther; but its principal use is for guiding the incision. As soon as the urine began to flow, Foubert, retracting the trocar a little, without drawing it quite out of the cannula, introduced the point of a slender knife into the groove in the cannula; and by the guidance of this groove he ran it onwards into the bladder, and was aware of the knife having actually entered this viscus, by the urine flowing still more freely. Then raising the knife from the groove, he made his incision, about an inch and a half in length, through the neck of the bladder, by moving the knife from that point at which it had entered, upwards towards the pubes. And, finally, by moving the handle more largely than the point of the knife, he opened the outer part of the wound to whatever extent the size of the stone seemed to require, and then withdrawing the knife, he introduced a blunt gorget to guide the forceps.

An effort was made by Thomas to improve this method; but he failed, and it was never much adopted. The inability of many bladders to bear distention is an insuperable objection; for, without this, the trocar is liable to pass between the bladder and rectum, and even through the bladder into the pelvis.—(*Mémoirs de l'Acad. de Chir.* 663, *vol.* 2. *Le Dran's Parallèle. Sharp's Critical Inquiry. J. Bell's Principles*, *vol.* 2.)

In the year 1748, Frère Côme's method of performing the lateral operation began to attract considerable notice. The operation was done with a particular instrument, called the *lithotome caché*, by means of which the prostate gland and orifice of the bladder were divided, from within outwards. The *lithotome caché* is entitled to much attention because it is still generally used in several parts of the continent and sometimes in this country, especially by the surgeons of the Westminster Hospital. "In France (says M. Roux) if there is any mode of operating more common than others, and preferred by the majority of practitioners, it is that in which the instrument named the *lithotome caché* is employed."—(See *Parallèle de la Chirurgie Angloise, &c. p.* 318.) Frère Côme does not ascribe the invention of this instrument to himself; but acknowledges that it resembles the knife for operating upon herniæ, said to have been devised by a French surgeon of the name of Bienaise. It consists of a handle and the blade part. The latter is slightly curved, about as thick as a quill, furnished with a beak, and excavated so as to form a sheath for a knife of its own length. By means of a kind of lever, the knife can be made to pass out of the sheath, and the distance to which the blade projects, also admits of being regulated with precision. For this purpose, the handle is divided into six sides, numbered 6, 7, 9, 11, 13, and 15, and which, according as they are more or less elevated, allow the lever to be depressed in different degrees, and the knife to move out of its sheath in the same proportion. Thus, the surgeon can at his option make an incision through the prostatic portion of the urethra and orifice of the bladder of six different lengths.

When the lithotome caché is to be used, the patient must be placed in the same posture as in every other mode of practising the lateral operation; and after a staff has been introduced, an oblique incision is to be made from the raphe of the perinæum, to a point situated rather more towards the anus than the innermost part of the tuberosity of the ischium. The bulb of the urethra should not be cut, and not too much of the membranous part of the urethra. The fat and transverse muscles having been divided, and the urethra opened, exactly as in the common operation, the scalpel is to be put down, and the beak of the lithotome introduced into the groove of the staff. Of course the surgeon, previously to the operation, will have settled the distance to which the blade of the instrument is to pass out of the sheath, and which must necessarily depend upon the age of the subject, and the presumed size of the calculus. When the beak of the lithotome has been inserted in the groove of the staff, the surgeon is to take hold of the handle of the latter instrument with his left hand, and bring it a little towards himself, at the same time pushing the lithotome into the bladder, with the handle depressed as much as possible. The staff is now to be withdrawn, and the surgeon is to try to feel the stone with the sheath of the other instrument, in order to be able to judge of the size of the calculus, and whether the distance to which the blade of the knife is intended to move out of the sheath, is such as is likely to make an opening of due but not unnecessary magnitude. Things being properly determined, the lithotome is to be held in a position calculated to make a division of the parts *which is parallel to the cut in the integuments*, and, by means of the lever, the cutting blade of the instrument is then to be disengaged from its sheath. The surgeon is next to draw the opened lithotome towards himself, in a perfectly horizontal manner, so as to make the requisite division of the prostate gland and orifice of the bladder.

As Sabatier observes, Frère Côme's method undoubtedly possesses all the advantages of the lateral operation, besides being more easy than Cheselden's plan, and most of the other modes subsequently proposed for cutting the prostate gland and orifice of the bladder with perfect smoothness, and to a sufficient extent to allow the calculus to be removed without any laceration of the parts.—(*Médecine Opératoire*, *t.* 3, *p.* 199.)

Several objections have been urged against the use of the lithotome caché.

1. It is said that the size of the incision is not always proportioned to the distance to which the knife moves out of the sheath; and that the instrument, when opened to No. 13 or 15, sometimes makes a smaller incision than when opened to No. 5 or 7. This uncertainty is said to depend upon the greater or less contraction of the bladder in different subjects.

For my own part, I confess that I am not inclined to put much credit in the accuracy of this last explanation, and suspect that the difference sometimes observed must depend upon the operator not taking care to draw out the instrument in a horizontal direction, a thing which may always be easily done.

2. Frère Côme himself made his incision too high, so that an extravasation of urine in the scrotum followed some of his operations; but the above method of operating is free from any objections of this kind.

3. Some surgical writers exaggerate the danger of cutting the body of the bladder too extensively with the lithotome, and thus producing internal hemorrhage. However, this cannot happen unless the surgeon raise the handle of the instrument improperly at the moment of withdrawing it, and, as Sabatier himself allows, it is rather the fault of the operator than of the operation.

4. The arteria pudica profunda and the rectum, which some authors conceive to be endangered, must always be in absolute safety, if the edge of the knife of the lithotome be turned in the direction above recommended.

I think that for a surgeon who understands the right principles of lithotomy, this is one of the best ways of performing the operation.

When I was at Paris, in 1815, I saw Dr. Souberbielle operate very skilfully with the lithotome caché. A stone of considerable size was extracted from a gentleman who was, I should think, not less than 70. No apprehensions were entertained of ill success, as I understood that this operator hardly ever lost a patient.

M. Roux, when he visited England, seems not to have been informed, that at the Westminster Hospital, the lithotome caché has been commonly employed for many years past. It has also been sometimes used at Guy's Hospital by Sir A. Cooper. When M. Roux likewise finds fault with the bad construction of this instrument, as made in London, I suspect that he cannot have seen those which are made and sold by Mr. Evans.—(See *Voyage fait à Londres, ou Parallèle de la Chirurgie Angloise, &c. p.* 318.)

Dupuytren has sometimes employed a lithotome caché, formed with two blades, with which the prostate gland is completely divided into an anterior and posterior portion: the staff is introduced; the membranous part of the urethra opened so as to let the lithotome be passed into the bladder; and when the instrument is withdrawn it divides the prostate on each side. In this method the vasa deferentia, rectum, transverse arteries of the perinæum, and the pudic artery, are avoided.

Le Cat, a surgeon of Rouen in Normandy, devised a mode of lithotomy, which would be too absurd to be described, were it less renowned. He thought the neck of the bladder might be dilated like the wound, and his operation was deformed with all the cruelty of the

Marian method, and every error attendant on the infant state of the latter operation. He first introduced a long wide staff; he cut forwards with a common scalpel through the skin and fat, till he could distinguish the bulb, the naked urethra, and the prostate gland. Secondly, with another knife, the urethrotome, having a groove on one side, he opened the urethra just before the prostate, and fixing the urethrotome in the groove of the staff, and holding it steady, rose from the kneeling posture in which he performed the outward incision. Thirdly, holding the urethrotome in the left hand, he passed another knife, the cystotome, along the groove of the urethrotome; and the beak of the cystotome being lodged in the groove of the urethrotome, it was pushed forwards through the substance of the prostate gland into the bladder. Fourthly, drawing the cystotome a little backwards, he gave the staff to an assistant to be held steadily, and lifting a blunt gorget in the right hand, he placed the beak of it in the groove of the cystotome, and pushed it onwards till it glided from the groove of the cystotome, along the groove of the staff into the bladder. Then, true to the principles of the apparatus major, and never forgetting his own peculiar theory, *little incision and much dilatation*, he forced his fingers along the gorget, dilated the neck of the bladder, and so made way for the forceps.—(*J. Bell's Principles, vol.* 2.)

In 1741, Le Dran described an operation, the introduction of which has been claimed by several since his time. A staff being introduced, and two assistants keeping open the patient's knees, while a third stands on one side of him on a chair (Le Dran says), "I then raise up the scrotum, and directing the last assistant to support it with both hands, so as to avoid bruising it, by pressing it either against the staff or the os pubis, I place his two fore-fingers on each side of the part where the incision is to be made; one of the fingers being laid exactly along that branch of the ischium, which rises towards the pubes, and the other pressed upon the raphe, that the skin may be kept fixed and tight. While I thus place the fingers of the assistant who supports the scrotum, I still keep hold of the handle of the staff, and direct it so as to form a right angle with the patient's body; at the same time taking care that the end of it is in the bladder. This position is the more essential, as all the other instruments are to be conducted along the groove of this. If the handle of the staff were kept inclined towards the belly, the end of it would come out of the bladder, and the gorget, missing its guide, would slip between that and the rectum.

"The staff being rightly placed, I take the knife from the assistant who holds the instruments, and put it into my mouth; then pressing the beak of the staff against the rectum, I feel the curvature of it through the perinæum. The incision ought to terminate an inch and a half below where we feel the bottom of the curvature. If we do not carry this incision sufficiently low, it may happen not to be of a size to allow the extraction of a large stone, and might lay us under the necessity of extending it farther afterward, for the skin will not lacerate here, nor easily give way for the passage of the stone. I therefore begin the incision from the lower part of the os pubis, continuing it down to the place that I before directed for its termination; after which I pass the point of the knife into the groove of the staff, and cutting from below upwards, without taking the point out of the groove, I open the anterior part of the urethra as far as the incision that is in the skin.

"The beak of the staff, which was pressed upon the rectum, must now be raised and pressed against the os pubis. At the same time I turn the handle towards the right groin, that the groove, which is at the beak of the staff, may face the space between the anus and the tuberculum ischii on the left side. Then carrying the point of the knife down the groove, I slide it along the beak, turning the edge that it may face the space between the anus and tuberosity of the ischium. By this incision, I exactly divide the bulb of the urethra; and by doing this on its side we are sure to avoid wounding the rectum, which, for want of this precaution, has been often cut. This first incision being made, I again pass the point of the knife into the curvature of the staff to the part where it bears against the perinæum, and direct it to be held there by the assistant, who supports the scrotum. This done, I take a large director, the end of which is made with a beak, like that of a gorget, and conveying this beak upon the blade of the knife, into the groove of the staff, I draw the knife out. I then slide the beak of this director along the groove of the staff into the bladder, and I withdraw the staff by turning the handle towards the patient's belly. The following circumstances will sufficiently satisfy us that the director is introduced into the bladder: first, if it strikes against the end of the staff, which is closed; secondly, if the urine runs along the groove. I next feel for the stone with this director, and, having found it, endeavour to distinguish its size and surface, in order to make choice of a proper pair of forceps; that is, one of a stronger or weaker make, or of a large or small size, agreeably to that of the stone; after which I turn the groove towards the space between the anus and tuberosity of the ischium, and, resting it there, convey a bistoury along the groove, the blade of which is half an inch broad, and about three-quarters of an inch long. I continue the incision made by the knife in the urethra, and entirely divide the prostate gland laterally, as also the orifice of the bladder; and I am very certain that the introducing the use of these two instruments, which are not employed by other lithotomists, does not prolong the operation a quarter of a minute, but rather shortens the time, both by facilitating the dilatation that is afterward to be made with the finger, and by rendering the extraction of the stone more easy. The bistoury being withdrawn, the groove of the director serves to guide the gorget into the bladder. I then introduce my fore-finger along the gorget (which is now easily done, as the urethra and prostate, being divided, do not oppose its entrance), and with it I dilate the passage for the stone in proportion to the size of which I discover it to be. This dilatation being made, I withdraw my finger and use the proper forceps."—(*Le Dran's Operations, ed.* 5, 1784, *London.*)

Pajola, of Venice, was the pupil of Le Cat, and his method resembles that of his master. He is stated to have cut for the stone 550 patients with success; which deserves notice, because his operation has for its principles dilatation and no division of any part of the bladder. He makes an incision into the groove of the staff with a lancet-pointed, double-edged knife, called an urethrotome, the blade of which has upon its centre a groove that is continued to its very point, and serves to guide the beak of another instrument, called the cystotome, into the groove of the staff. As the professed intention of the cystotome is only to cut the prostate gland, its name is ridiculous. It consists of a handle and very slender blade, which is not connected with the handle, but with its sheath, by means of a little joint close to the beak of the instrument. When the cystotome is opened as far as possible, the end of the blade farthest from the beak is twelve lines from the sheath. In this position it is held by a transverse piece of steel, which admits of being pushed more or less out at the option of the surgeon, and can be fixed by means of a screw. Pajola, like Scarpa, considers cutting the neck of the bladder dangerous, and he merely divides the prostate, after which he introduces a blunt gorget, and along this a species of forceps for dilating the neck of the bladder in all directions.—(*X. F. Rudtorffer über die Operation des Blasensteins nach Pajola's Methode.*) As Langenbeck observes, great as the success of this lithotomist has been, his method of operating has little to recommend it; and every thing must be ascribed to his individual skill and intimate knowledge of the parts. Langenbeck even prefers Le Cat's method, in which there is no need of such a multiplicity of instruments. The blunt gorget and dilator are perfectly unnecessary, as the finger would do the purpose of both.

In some former editions of this Dictionary, I omitted to notice what has been termed by the French, "*Opération à deux temps*," and which was first mentioned by Franco. If by this plan it be intended, that the incision should be made at one period, and the extraction of the stone not attempted till a subsequent period, I cannot too strongly reprobate the practice. But if I am to understand, that the postponement of the completion of the operation is only to be adopted as a matter of necessity, when the patient cannot bear the longer continuance of the unsuccessful efforts to extract the stone, of course I can only say, that every endeavour should be used to avoid this very disagreeable dilemma, by making in the first instance an adequate opening,

and (if this cannot be done) by breaking the calculus, and carefully removing all the fragments. Some farther considerations against delaying the completion of the operation, will be found in the last two editions of the *First Lines of Surgery*.

The danger of the beak of the gorget slipping out of the groove of the staff, is one of the chief objections urged against the employment of the first of these instruments. In order to obviate this inconvenience, Sir Charles Blicke had the groove of the staff and the beak of the gorget so constructed, that they locked into each other, and continued fixed till near the extremity of the staff. The contrivance, though plausible and ingenious, is not much used: the point of contact of the beak and body of the instrument is necessarily so small that it is liable to break. It is allowed, however, that this objection might be removed; but another one is still urged, viz. the beak and groove catching on each other, so as to resist the efforts made to introduce the gorget into the bladder. Every operator knows, that much of the safety of the lateral operation, as performed at present, depends on the ease with which the beak of the gorget slides along the groove of the staff. Le Cat, in 1747, is said to have devised a similar instrument.

Some operators have a good deal of trouble in dissecting into the groove of the staff. Sir James Earle invented an instrument to render this part of the operation more easy. It consists of a short staff, with an open groove, connected by a hinge with the handle of another staff of the usual size, shape, curvature, and length, which may be called the *long staff*. The hinge, by means of a pin, is capable of being disjointed at pleasure. The short staff is sufficiently curved to go over the penis and scrotum, and long enough to reach to that part of the long staff which is just below the beginning of its curvature. The end of the short staff, made somewhat like a pen, with the sides sharpened and finely pointed, is adapted to shut into the groove of the long staff, and its cutting edges are defended from being injured by a proper receptacle, which is prepared for it in the groove of the long staff. When the instrument is shut, the groove of the short staff leads into that of the long one, so as to form one connected and continued groove. The short staff is rendered steady by the segment of an arch, projecting from the long one through it.

The long staff, separated from the short one, is first introduced in the usual manner, and the stone having been felt, the short staff is to be put on the other at the hinge. The incision is then to be made in the usual manner through the skin and cellular membrane, and a second incision through the muscles, so as nearly to lay bare the urethra. The operator then being perfectly convinced that the extremity of the long staff is sufficiently within the bladder, must bring the end of the short staff down, and press it against the urethra, which it will readily pierce, and pass into the cavity prepared for it in the groove of the long staff. The two pieces being now firmly held together by the operator's left hand, nothing remains to be done except applying the beak of the gorget to the groove of the short staff, and pushing it on till it is received in the groove of the long one; and if this latter be made with a contracted groove, it will just enter where the contraction begins, and thus must be safely conducted into the bladder.—(*Earle on the Stone; Appendix, ed.* 2, 1796.) Deschamps describes an instrument invented by Jardaa, surgeon of Montpellier, which bears a resemblance to Earle's double staff, but was more complicated, being designed to support the scrotum, and also press the rectum out of the way.

The late Mr. Dease of Dublin, and Mr. Muir of Glasgow, considering that the gorget was more apt to slip from the staff in consequence of the latter being curved, and that its beak never slips from the groove of the staff in operating on women, proposed, like Le Dran, to convert the male into the female urethra. They introduce, as usual, a curved grooved staff into the bladder, make the common incisions, and open the membranous part of the urethra; but instead of introducing a gorget on the curved staff, they conduct along the groove a straight director or staff into the bladder, and immediately withdraw the other. The gorget is then introduced. In this manner the operation may be very well performed with a narrow bistoury, as was advised by Mr. A. Burns. Mr. Key, who adheres to the valuable principles of Cheselden, but uses a knife instead of a gorget, is also an advocate for a director which is straight except towards its termination, a part never concerned in guiding the knife, and which is introduced like the common staff. —(*On the Section of the Prostate Gland, p.* 23.)

LITHOTOMY, AS PERFORMED WITH A KNIFE INSTEAD OF A CUTTING GORGET BY SEVERAL OF THE MODERNS.

We have already described how Frère Jacques and Cheselden used to operate with a knife, without any cutting gorget, in the early state of the lateral operation. The success which attended the excellent practice of the latter surgeon certainly far exceeds what attends the present employment of the gorget; for out of 52 patients, whom he cut successively for the stone, he lost only two; and out of 213 of all ages, constitutions, &c. only 20. These facts are strongly in favour of abandoning the use of the gorget, and doing its office with a knife.

The objections to the gorget are numerous and well founded. In the hands of many skilful operators, its beak has slipped out of the groove of the staff, and the instrument has been driven either between the rectum and the bladder into the intestine instead of the latter viscus, or else between the bladder and the pubes. "If I were to be asked (says Sir A. Cooper) how many times I have known the gorget slip and pass between the bladder and rectum, I should say at least a dozen times, and in each case the most lamentable and fatal consequences ensued; for the operator now lays hold of the stone and bladder together; the forceps slip; the stone, enclosed in the bladder, is again laid hold of; and thus he continues to pull, bruise, and injure the bladder, till the patient is at length carried back to his bed with the stone unextracted, violent inflammation supervenes from the injury done to the bladder, and in a few days the patient is no more."—(See *Lancet, vol.* 2, *p.* 238.) Sir James Earle remarks: "I have more than once known a gorget, though passed in the right direction, pushed on so far, and with such violence, as to go through the opposite side of the bladder." Bromfield, even when operating with a blunt gorget, perforated the bladder and peritoneum, so that the abdominal viscera came out of the wound.—(*P.* 270.) I now know of at least three instances in which the gorget, slipping from the staff, completely severed the urethra from the bladder; the stone was not taken out, and the patients died.

We will suppose, however, that the preceding dangers of the gorget are surmounted, as they certainly may be, by particular dexterity, seconded by the confidence of experience. The gorget is introduced; but whatever kind of one has been used, the wound is never sufficiently large for the easy passage of any stone, except such as are below the ordinary size. Camper has noticed this fact: "Hawkensius solo conductore, cujus margo dexter in aciem assurgit, idem præstat: *omnes plagam dilatant ut calculum extrahant: dilacerentur igitur semper vesica ostium et prostata.*"—(P. 114.) Dease says: "In all the trials that I have made with the gorget on the dead subject, I have never found the opening into the bladder sufficiently large for the extraction of a stone of a middling size, without a considerable laceration of the parts. I have frequently taken the largest sized gorget, and could not find, in the adult subject, I ever entirely divided the prostate gland, if it was any way large; and in the operations that were performed here on the living subject, if the stone was large the extraction was painfully tedious, and effected with great difficulty, and in some cases not at all."

I shall dismiss this part of the subject with referring the reader to the spirited and correct remarks on the objections to the gorget in Mr. John Bell's *Principles, vol.* 2, *part* 2.

The latter author recommends the external incision in a large man to commence about an inch behind the scrotum, and to be carried downwards three inches and a half, midway between the anus and tuberosity of the ischium. The fingers of the left hand, which at first kept the skin tense, are now applied to other purposes. The fore-finger now guides the knife, and the operator proceeds to dissect through fat and cellular substance, and muscular and ligamentous fibres, till the wound is free and open, till all sense of stricture is gone; for it is only by feeling opposition and stricture

that we recognise the transverse muscle. When this hollow is fairly laid open, the external incision, *which relates merely to the free extraction of the stone, is completed.* If it were the surgeon's design to operate only with the knife, he would now push his fingers deeply into the wound, and, by the help of the fore-finger, dissect from the urethra along the body of the gland, till he distinguished its thickness and solidity, and reached its back part. Then plunging his knife through the posterior portion of the gland, and settling it in the grove of the staff, he would draw it firmly and steadily towards him, at the same time pressing it into the groove of this instrument; and then the free discharge of the urine assuring him that the prostate and orifice of the bladder were divided, he would lay aside his knife, pass the left fore-finger into the bladder, withdraw the staff, and introduce the forceps.—(*John Bell, p.* 197.)

Mr. C. Bell describes the following method of operating with a knife instead of a gorget. A staff grooved on the right side, a scalpel with a straight back, and the common lithotomy forceps are the indispensable instruments. The staff is kept in the centre, and well home into the bladder. The surgeon making his incision under the arch of the pubes and by the side of the anus, carries it deeper towards the face of the prostate gland; cutting near to the staff, but yet not cutting into it, and avoiding the rectum by pressing it down with the finger. Now carrying the knife along the staff, the prostate gland is felt. The point of the knife is run somewhat obliquely into the urethra, and into the lateral groove of the staff, just before the prostate gland. It is run on until the urine flows. The fore-finger follows the knife, and it is slipped along the back of it, until it is in the bladder. Having carried the fore-finger into the bladder, it is kept there and the knife is withdrawn. Then the forceps, directed by the finger, are introduced.—(*Operative Surgery, vol.* I, *p.* 361.)

Mr. Allan Burns recommends the following method: "The plan (says he) introduced by Cheselden, and revived by Mr. J. Bell, I would assume as the basis of the operation; but still, along with their mode I would blend that of Mr. Dease, by which, I imagine, we may overcome some of the disadvantages attendant on each considered individually.

"For more than twelve months I have been in the habit of showing such an operation, which is as simple in its performance as the one in general use, is attended with less danger to the patient, permits of an incision varying in size according to the wish of the operator, and completely prevents injury of the rectum or pudic artery. To perform this operation, I introduce into the urethra a common curved staff, then make the usual incision into the perinæum, divide fully and freely the levator ani, so as to expose the whole extent of the membranous part of the urethra, the complete extent of the prostate gland, and a portion of the side of the neck of the bladder. When this part of the operation is finished, I open the membranous part of the urethra, and introduce through the slit a straight or female staff, with which I feel the stone, and then withdraw the curved staff. This done, I grasp the handle of the staff firmly in my left hand, and with the right lay hold of the knife. Having ascertained that the two instruments are in fair contact, I rest the one hand upon the other, pressing them together, and then, by a steady extraction, I pull out the knife and staff together, which is preferable to drawing the knife along the staff: it prevents the risk of the one slipping from the other; it guards the bulb of the urethra, and every other part, from injury; for between them and the cutting instrument the staff is interposed," &c. "When introducing the knife, the side of the blade must be laid flat along the fore-finger of the right hand, which is to project a little beyond the point. In this state the finger and knife are to enter the wound opposite the tuber ischii; but in proportion as they pass along, they are to be inclined forwards, till at last, with the point of the finger, the staff is to be felt through the coats of the bladder, a little beyond the prostate, and rather higher than the orifice of the urethra. Here the knife is to be pushed with the finger through the bladder, and when the point is fairly fixed in the groove of the staff, the operation is to be finished by the steady extraction of both instruments"—(See *Edin. Surg. Journal, No.* 13.)

The knife of Cheselden does not require so much violence to divide the parts as the gorget does; cannot slip in some instances before, in others behind, the bladder; and it will make a wound sufficiently ample for the easy extraction of the stone, without the least laceration. The possibility of its wounding the rectum, Dr. Thomson thinks might be obviated by employing it as follows: "After having made the external incisions, and divided the membranous part of the urethra in the way that it is usually done for the introduction of the beak of the gorget, a straight grooved staff is to be introduced into the groove of the curved staff, and pushed along it into the bladder. The curved staff is then to be withdrawn, and the surgeon, laying hold of the handle of the straight staff with his left hand, and turning the groove upwards and a little outwards, presses the back of it downwards towards the right tuber ischii, and holds it steadily in that position. The point of a straight-backed scalpel being now introduced into the groove of the staff, with its cutting edge inclined upwards and a little outwards, is to be pushed gently forwards into the bladder. The size of the scalpel need only be such as will make a wound in the prostate gland and neck of the bladder, sufficiently large to admit the fore-finger of the left hand. The scalpel being removed, this finger is to be introduced into the bladder through the wound which has been made, and the staff may then be withdrawn. With the finger the surgeon endeavours to ascertain the size and situation of the stone. If after this examination he judges the incision in the neck of the bladder to be too small for the easy extraction of the stone, he next introduces into the bladder a straight probe-pointed bistoury, with its side close to the fore part of his finger, and its cutting edge upwards. By turning this edge towards the left side, and by keeping the point of his finger always beyond the point of the bistoury, he may safely divide, in the direction of the first incision, as much of the prostate gland and neck of the bladder as he shall deem necessary."—(See *Obs. on Lithotomy, &c. with a Proposal for a New Manner of Cutting for the Stone, Edin.* 1808.)

Mr. Allan, who is a strenuous advocate for using the knife instead of the gorget, directs us, after laying bare the urethra, and bringing the staff so as to form a right angle with the patient's body, to feel that the instrument is fairly lodged in the bladder. The operator is to use the fore-finger of his left hand as a director in feeling for the groove in the staff, and in distinguishing the prostate gland; and with this finger he is to depress the rectum, and direct the deeper part of his dissection. "Feeling the gland with the point of the fore-finger of the left hand, and the groove of the staff in the upper part of the wound, the assistant is desired to steady his hand, and the operator, holding his knife as he does a writing pen, his fingers an inch and a half from the point, turns up its edge towards the staff, and strikes its point through the membranous part of the urethra into its groove, half an inch before the prostate gland. He now turns the back of the knife to the staff, slides it a little backwards and forwards in the groove, that he may be sure it has fairly entered; then shifts the fore finger, with which he guides the incision, places it under the knife, and always keeps it before its point, so as to prevent the rectum from being wounded; he then lateralizes the knife, enters the substance of the prostate, is conscious of running the scalpel through its solid and fleshy substance, and judges by the finger of the extent of the incision which he now makes. The urine flows out; he slips his finger into the opening, withdraws the scalpel, and gives it to an assistant, who hands him the forceps, which he passes into the bladder, using the fore-finger of his left hand, which is still within the wound, as a conductor. The forceps instantly encounter the staff, which serves to conduct them safely into the bladder, while the finger guides them through the wound, &c."—(*Allan on Lithotomy, p.* 48, *Edin.* 1808.)

I leave the reader to judge, which of the foregoing modes of operating with a common knife claims the preference. Perhaps Cheselden's manner, which is also Mr. John Bell's, is as deserving of recommendation as any. When it is adopted, a largish scalpel, with a long handle, will be found more convenient than a common one, on account of the depth of the parts requiring division, especially in adults and fat subjects.

I would also beg the attention of surgeons to the modification in the manner of performing Cheselden's operation, proposed by Mr. Key, and executed with a staff of nearly a straight form, and a scalpel that has a slightly convex back near its point, in order that it may run with more facility in the groove of the staff. —(*On the Section of the Prostate Gland*, p. 26.)

The methods of operating with a knife, as practised by Klein and Langenbeck, I shall not here repeat, as they are described in the last edition of the *First Lines of Surgery*, accompanied with many valuable practical observations made by these judicious and skilful surgeons.

That the performance of lithotomy with a knife, when the operator has the assistance of a proper staff, cannot be difficult, may be inferred from there being no particular difficulty in the method, even when no staff at all is employed. In the spring of the year 1814, when at Oudenbosch in Holland, I was requested by Sergeant Ryan, of the 1st Foreign Veteran Battalion, to see his little boy, about four years old, who was troubled with symptoms which made me immediately suspect that there was a stone in the bladder. As I had no sound, I introduced into this viscus a small silver catheter, which distinctly struck against a calculus. Without taking the instrument out again, I determined to perform lithotomy with a common scalpel. Indeed, no other mode could be adopted, as we had neither staff, gorget, nor lithotomy instruments of any kind. After making the external part of the incision in the common way, I found that the catheter afforded me no guidance. I therefore withdrew it, and dissected deeply by the side of the prostate gland, till the fore-finger of my left hand passed rather beyond it. The scalpel was then plunged into the bladder, behind this gland, under the guidance of my left fore-finger, and with the edge turned towards the urethra. The necessary division of the prostate and neck of the bladder was then made by cutting inwards and upwards in the direction of the rest of the wound. With a small pair of ordinary dressing forceps, a calculus, rather larger than the end of the thumb, was easily extracted. This operation was done at the Military Hospital, in the presence of Dr. Shanks, of the 56th regiment, and several other medical officers. Not a single bad symptom ensued, although the army unexpectedly moved into the field three days afterward, and the child travelled about for some time in a baggage cart, in an exposed and neglected state. The wound was consequently rather longer in healing than usual; but this was the only ill effect. The little boy in the end completely recovered.

Of late years, many surgeons have chosen to perform lithotomy with beaked scalpels. The practice, indeed, is still gaining ground. Mr. Blizard's knife is one of the best. Its blade is long, straight, and narrow, and, like the gorget, is furnished with a beak, by means of which it admits of being conducted along the groove of the staff into the bladder, after the external incisions have been made. The staff is then withdrawn, and the operator has now the power of making the incision through the prostate gland and orifice of the bladder downwards and outwards to any extent which the parts will allow or the case require. This is one of the principal advantages which beaked long narrow knives have over gorgets, which, after their introduction, cannot be farther used for the enlargement of the wound. The narrow knife will also cut more safely downwards and outwards than any gorget: nor is it subject to the serious danger of slipping away from the staff, and going we know not where; because the moment its beak and extremity have entered the bladder, the staff is no longer necessary, as the proper extent of the blade will then readily pass in without the aid of any conductor at all. I need hardly observe, also, that in this method we have nothing like the perilous and violent thrust of the gorget, which, in the event of a little unsteadiness in the operator's hand, or of any fault either in the position of the staff, or the direction of the gorget, will do irremediable and fatal mischief.

Sir A. Cooper admits, that the operation may be done very well with a knife in children; but he prefers a gorget, or the *bistoire caché*, for old persons, on account of the prostate gland and bladder being frequently so rigid in them, that the scalpel does not easily make an impression upon those parts. Also, for adults, he has relinquished the use of the knife, in consequence of the unfitness of it to do what is necessary in a deep perinæum.—(See *Lancet*, *vol.* 2, *p.* 340.)

A FEW GENERAL REMARKS ON THE BEST MODE OF MAKING THE INCISION IN THE LATERAL OPERATION; AND SOME REFLECTIONS ON THE PRINCIPLES INCULCATED BY PROFESSOR SCARPA.

Perhaps, of all the great operations in surgery, lithotomy is that in which great awkwardness, mortifying failures, and dangerous blunders, are most frequently observed. Many a surgeon, who contrives to cut off limbs, extirpate large tumours, and even tie aneurismal arteries, with *éclat*, cannot get through the business of taking a stone out of the bladder in a decent, much less a masterly, style. This fact is so familiarly known in the profession, and its truth so often exemplified, that I may well be excused the unpleasant task of relating in proof of it all the disasters which have fallen under my own notice. But I must take the liberty of remarking, that in this branch of surgery, a great number of individuals do not profit by these instructive lessons of experience. The more they see of lithotomy, the more they are convinced of its dangers; yet, too often, instead of studying the causes of ill success, they merely derive from the examples before them a suspicion of the unskilfulness of the operator, or some discouraging conjectures about the difficulties of the operation.

The establishment of certain principles to be observed in lithotomy, appears the most profitable way of diminishing the frequency of the accidents and failures of this common operation. If these principles are not violated, it is of less consequence what instrument is employed; for the surgeon may do nearly the same thing with an ordinary dissecting knife, a concealed bistoury, a beaked scalpel, or a well-made gorget.

After the very opposite principles and different methods of cutting for the stone which are explained in the preceding columns, as preferred by different surgeons, I think it may be useful to offer a few general observations on the proper direction and size of the incision. These points, which are of the highest practical consequence in regulating the principles which ought to be observed in lithotomy, are far from being settled, as must be plain to every body who recollects that Desault, Mr. John Bell, Klein, and Langenbeck have recommended a free opening; Scarpa, Callisen, and others, a small one; or, as Scarpa objects strongly to my calling his incision small, I will say one extending from the apex of the prostate gland to the orifice of the bladder, no part of which is divided; that Mr. Abernethy and Scarpa employ gorgets, which cut upwards and outwards, at angles of 45° and 69° from the axis of the urethra; and that the gorgets of Cruikshank, B. Bell, Desault, Mr. Cline, and most other surgeons, are intended to cut either directly outwards, or outwards and downwards.

The incision through the whole of the parts cut in lithotomy, should always be made in a straight, regular, direct manner, from the surface of the skin in the perinæum to the termination of the wound in the urethra and bladder. In an adult subject, the external wound should commence about an inch above the anus. The impropriety of beginning it higher up has been duly insisted upon by Sharp, Bertrandi, Callisen, and every good writer on the operation. "Il ne faut couper l'urétre que le moins qu'on peut, parcequ'on obtient par ce moyen une meilleure voie pour pénétrer dans la vessie sous l'angle du pubis. C'est avec raison que Sharp dit que l'incision de l'urétre faite au-dessus de cet angle est si peu utile pour l'extraction de la pierre, qu'on n'en retireroit pas plus d'avantage en le coupant presque dans toute sa longueur."—(*Bertrandi, Traité des Opérations*, *p.* 127.) And Callisen lays it down as a maxim: "Ut eæ partes haud sectione attingantur, quæ pro calculi egressu nihil faciunt; adeoque bulbus urethræ, et hujus pars corpore spongioso circumdata intacta relinquatur."—(*Systema Chirurgiæ Hodiernæ pars posterior*, *p.* 655.)

Extraordinary as it may seem, it is not the less true, that cutting too much of the urethra is one of the most common faults still committed by modern surgeons. The incision in the integuments is to be large, that is to say, at least three inches in length in an adult subject, because a free opening in the skin is not only exempt from danger but attended with many advantages, es-

pecially those of facilitating the other steps of the operation, and preventing any future lodgement and effusion of urine. The external wound ought to be directed towards a point situated a very little towards the anus from the innermost part of the tuberosity of the ischium. From the line thus made the incision should be carried inwards and upwards through all the parts between it and the side of the prostate gland. Another line, extending from the inferior angle of the wound to the termination of the cut in the bladder, forms the precise limits to which the depth of the incisions should reach, and no farther.

The great principle of making the axis of the wound as straight and direct as possible, should always be kept in view, whether the surgeon employ a common scalpel, which cuts into the bladder from without inwards, or other instruments which divide the prostate gland and neck of the bladder from within outwards, like the bistoire caché, beaked knives, and every kind of cutting gorget. In the latter circumstance, the only difference consists in cutting, from the bladder and urethra, downwards and outwards *towards a point situated between the anus and the tuberosity of the ischium*, instead of carrying the incision from this point, upwards and inwards, through the side of the prostate gland and the orifice of the bladder. The following may be enumerated as important advantages of attending to the foregoing principle:

1. The wound is made in that direction which affords the greatest room for the extraction of large stones; and the axis of the incision being also as nearly straight as possible, the introduction of forceps, and the passage of the calculus outwards, are materially facilitated.

That these are important advantages I think every surgeon will allow, who knows how much the pain and danger of lithotomy depend upon the injury which the parts suffer from the force sometimes used in the extraction of the stone, and the repeated introduction of the forceps. Cheselden, one of the most successful lithotomists England ever produced, made the incision in the direction here recommended; sometimes inwards and upwards, sometimes outwards and downwards.—(See *Key on the Section of the Prostate Gland*, p. 27.) The following remarks of another excellent surgeon merit particular attention:—"J'ai vu plusieurs fois dans les hôpitaux de Paris, que les chirurgiens, coupant trop en haut vers l'angle du pubis, sentoient une grande résistance au périné, quand ils vouloient retirer le calcul avec les tenettes; on voyoit le périné se tuméfier par la pression qu'y faisoit la pierre; en ce cas, quelques operateurs plus sages abandonnoient la pierre, introduisoient de nouveau le gorgeret, et en tournant en dessous la cannelure de celui-ci, prolongeoient l'incision obliquement vers la tubérosité de l'os ischion; et enfin, à la faveur de cette plus grande ouverture, retiroient la pierre sans causer de déchiremens."—(*Bertrandi, Traité des Opérations*, p. 133.) Larger stones may likewise be thus extracted, without being broken, than in any other mode of making the lateral incision, as must be obvious to every practitioner who recollects the very limited room afforded at the upper part of the triangular space, between the arch of the pubis, the ramus of the ischium, and the neck of the bladder. This consideration cannot fail to have great weight with all surgeons who feel duly convinced how unsatisfactory a method it is to break a calculus in order to get it out of the bladder. The measures necessary for the removal of all the fragments protract the completion of the operation, and seriously increase its danger; while the continuance of a single part of the stone behind may cause a renewal of all the grievances for the cure of which the patient submitted to the operation. By these remarks, however, I am far from meaning to say that large calculi should not be broken: on the contrary, my only wish is that the necessity for the practice may be avoided as much as possible, by making a free incision into the bladder, and even enlarging the opening, if necessary, as far as can be done with safety. In short, instead of breaking the stone, I prefer the practice of the late Mr. Martineau, of Norwich, perhaps the most successful lithotomist that ever lived, as *out of* 84 *patients whom he cut, two only died;* a statement highly favourable to operating with a knife, and making an adequate opening. "Should the stone be large, or there be any difficulty in the extraction, rather than use much force, while the forceps have a firm hold of the stone (says Mr. Martineau), I give the handles to an assistant, who is to draw them outwards and upwards, while the part forming the stricture is cut; which is easily done, as the broad part of the blade becomes a director to the knife: and rather than lacerate, I have often repeated this enlargement of the inner wound two or three times."—(See *Med. Chir. Trans. vol.* 11, *p.* 411.) The great advantage of the knife over the gorget, and even the necessity of employing it to adapt the size of the opening in the bladder to the magnitude of the stone or its fragments, are most convincingly exemplified in several cases recently put upon record. Thus Klein, with the aid of a common scalpel, extracted a calculus which weighed twelve ounces thirty grains, and the patient recovered.—(*Pract. Ansichten Bedeutendsten Operationen*, *h.* 1.) In 1818, Mr. Mayo of Winchester operated with a knife, and extracted a calculus, which broke in the forceps, weighing fourteen ounces two drachms avoirdupois, and the patient recovered.—(See *Med. Chir. Trans. vol.* 11, *p.* 54, *&c.*) Mr. W. B. Dickenson of Macclesfield, also succeeded, with Mr. Gibson's knife, in taking out of the bladder a calculus, the fragments of which weighed eight and a half ounces, and the patient was saved.—(*Vol. cit. p.* 61.) And in the same volume may be seen other instances, in which immense calculi were removed from the bladder with various results, but particularly one, which weighed sixteen ounces, and which Sir A. Cooper could not succeed in breaking: he was therefore obliged to enlarge the wound first made with the gorget "to the sacro-sciatic ligament," when with the aid of a hook applied to the fore part of the stone behind the pubes, and the simultaneous assistance of the forceps, he succeeded with considerable difficulty in removing this immense mass. The patient lived, however, only four hours after the operation.—(See *Med. Chir. Trans. vol.* 11, *p.* 73.)

2. The arteria pudica profunda can never be injured, because the surgeon does not let the knife or gorget approach nearer to the ischium than a point which is situated some way from the tuberosity of that bone towards the anus; and consequently the edge of the instrument cannot come into contact with the inside of the tuberosity and ramus of the ischium where the great pudic artery is situated.

3. The rectum will not be wounded, because the direction of the axis of the incision, either downwards and outwards to the above-mentioned point, or from that point inwards and upwards, sufficiently removes the edge of the knife or gorget from the intestine. But the rectum will be in still greater safety, if it be pressed downwards with the fore-finger of the left hand in the wound, and the prudent custom of emptying it by means of a clyster, a short time before the operation, be not omitted; for no lithotomist should ever forget, that when this bowel is considerably distended with feces, it rises up a little way on each side of the prostate gland.

4. As the seminal duct penetrates the lower part of the substance of the prostate gland in order to reach the urethra, and the knife or other instrument employed divides the side of that gland obliquely inwards and upwards, or outwards and downwards, the duct will not be in danger of being cut.

The judicious Callisen is well aware of the advantages of making a smooth, even, direct incision into the bladder;* but, like Professor Scarpa, he is averse to making a free cut through the neck of that viscus. Indeed, as we shall presently notice, Scarpa does not sanction cutting any portion of the bladder whatever.

Every practitioner who will take the trouble to look over the history of the lateral operation, will find that the greater number of lithotomists who have particularly distinguished themselves by their unparalleled success, as Frère Jacques, Cheselden, Côme, Mr. Martineau, Dr. Souberbielle, &c. made a free incision into the bladder. This fact alone is enough to raise doubts of the goodness of the advice delivered upon this subject by Callisen and Scarpa; especially as neither they nor any other modern surgeon (with the exception,

* Vulnus sit æquale, haud angulatum, conicæ figuræ, apice vesicam respiciente, externa plaga ampla, et quatuor pollicum longitudine, unde effluxus sanguinis, puris, lotii, arenæ, facilitatur.—(See *Systema Chirurgiæ Hodiernæ, pars posterior*, p. 656. *Hafniæ*, 1800.)

perhaps, of Pajola, whose individual skill is said by Langenbeck to make amends for the disadvantages of this method), can boast of having cut patients for the stone with a degree of success at all equal to that of the above-mentioned operators. The extraordinary success which characterized Cheselden's practice, we have already detailed. The accounts of the successful operations done by Frère Jacques and Côme are equally remarkable.

Mr. Martineau, as I have noticed, lost but two patients out of 84 on whom he operated, and this without making any selection, as he never rejected any case. His patients were always kept a week in the house before they were operated upon; and this precaution, with a regulated diet, and perhaps a dose or two of opening medicine was the only preparatory treatment. —(*Med. Chir. Trans. vol.* 11, *p.* 409.)

During my stay at Paris, in 1815, I saw Dr. Souberbielle extract a stone of considerable size on the plan of his well-known ancestor. The incision was ample and direct, so that the calculus was taken out with perfect ease. Now, as the operations of this professed lithotomist are very numerous, and he enjoys the reputation of scarcely ever losing a patient, are we not justified in inferring, that the advocates for a small opening are promulgating the worst advice which can be offered to the practitioner? My own observations certainly tend to such a conclusion, as will be presently explained. The tract lately published by Scarpa (*Memoir on the Cutting Gorget of Hawkins, &c. trans. by Wishart*) has for its main objects the recommendation of a modification of Hawkins's gorget, and the inculcation of the propriety of making a limited incision in the prostate gland without cutting any part of the bladder. As sufficient room cannot thus be obtained for the extraction of even a stone of moderate size, he is an advocate for the gradual dilatation of the urethra and orifice of the bladder. He observes, that the lateral operation, though executed with the greatest precision, does not exempt the surgeon from dilating in a certain degree the orifice of the bladder and cervix of the urethra, the dilatation of those parts, however moderate, being always necessary even where the calculus is of middling size. He states that in the adult the orifice of the bladder dilates almost spontaneously to the diameter of five lines; and he adds, that the lateral incision, within proper limits, divides the body and base of the prostate gland to the depth of four or at most five lines, forming with the five, to which the orifice of the bladder naturally yields, an aperture of ten lines. But, says Scarpa, in an adult, a stone of ordinary size and oval figure is sixteen lines in the small diameter, to which must be added the thickness of the blades of the forceps: consequently, even after the incision has been made with the most scrupulous exactness, the stone, though of moderate size, cannot pass out of the bladder, unless the dilatation of the base of the gland and orifice of the bladder be carried to the extent of nearly eight lines beyond the size of the aperture made with the knife. But, says Scarpa, if in order to avoid distending the parts to the extent of eight lines, the base of the prostate gland, together with the orifice of the bladder and a part of its fundus, be divided to a depth equivalent to it, *the event would necessarily be an effusion of urine into the cellular membrane, between the rectum and bladder, and consequently suppuration, gangrene, fistulæ, and other serious evils.*—(*P.* 4, 5.)

According to Scarpa, the apex of the prostate gland forms the greatest resistance to the introduction of the forceps and the extraction of the stone, and therefore ought to be completely divided (*p.* 7); but he contends that two, and sometimes three lines of the substance of the base of the gland should be left undivided; which, he asserts, is a matter of great importance, because the untouched portion around the orifice of the bladder, prevents the effusion of urine, and the formation of gangrene or fistulæ, between that part and the rectum.—(*P.* 22.)

After this statement of one of the great principles which Scarpa wishes to be observed in the performance of the lateral operation, a question or two naturally arise. Are we then to conclude, that the plan of making a free and direct incision into the bladder ought to be abandoned? Must we forget that it is this method which has answered so well in the hands of Cheselden and the several renowned lithotomists already enumerated? And must we believe that the advice delivered upon this point by Bertrandi, Desault, Mr. John Bell, and all the best modern surgeons in this country, is founded only upon a capricious partiality to the free use of cutting instruments?

Earnestly as I respect the names of a Callisen and a Scarpa, their authority cannot influence me farther than I find it coincide with the dictates of experience,—the great arbitrator of every disputed point in practice.

We have seen, that an apprehension of effusion of urine, gangrene, fistulæ, &c. is the only reason assigned by Scarpa for his aversion to making a complete division of the side of the prostate gland and orifice of the bladder. But I would inquire, do we find extravasation of the urine between the rectum and bladder, and gangrene, and fistulæ, so frequent after lithotomy in England, as to render it probable that these ill consequences can ever proceed from our usual mode of dividing completely, not only the side of the prostate gland, but also the adjoining part of the bladder? Are such bad effects so often experienced in this country, as to constitute a material source of uneasiness in the mind of a surgeon about to undertake lithotomy? Do they form a substantial reason for abandoning the maxim of always endeavouring, as far as circumstances will allow, to make an incision of sufficient size for the easy removal of the calculus? And would not Scarpa's method of stretching and dilating the wound, in order to get the stone out of the bladder, often dangerously prolong the operation; lead to much mischief from the repeated use of the forceps; cause serious contusion and laceration of the parts; and, for all these reasons, render inflammation of the bladder and peritoneum very likely to follow?

I have seen the lateral operation performed an immense number of times, either with various kinds of gorgets, beaked knives, the lithotome cache, or common scalpels. In all these examples, the avowed intention of the surgeon was to make a free opening into the bladder. I do not mean, however, to say, that this was always actually accomplished, since the bad construction of the instruments employed, and other causes, sometimes frustrated the wise design of the operator. But what was the consequence? Generally speaking, those surgeons who made only a small incision into the bladder, and kept their patients a long while upon the operating table, ere they succeeded in getting out the stone, by the repeated and forcible use of the forceps, had the mortification to see very few of their patients recover; a large proportion of them being carried off by peritonitis, on the third or fourth day after the operation.

On the contrary, when the incision was ample and direct, so that the calculus could be easily and gently removed, the patients were almost always saved.

For the first six or seven years of the long time during which I enjoyed frequent opportunities of seeing lithotomy performed in St. Bartholomew's Hospital, gorgets were invariably used, most of which made an insufficient opening. The consequence was, that many of the patients were detained a long while upon the operating table, before the stone could be extracted, and some considerable numbers were lost by peritonitis. Afterward, however, in the same institution, common scalpels and beaked knives were generally used; a freer opening was mostly made; and the proportion of deaths from peritonitis was strikingly lessened.

The following observation, made by Mr. Martineau, is also worthy of particular attention;—"In the first years of my practice," says he, "I was not very successful; and often witnessing many untoward circumstances in myself and others, which appeared to arise from the use of the cutting gorget, I determined to lay that instrument aside, and employ the knife only, and the *blunt* gorget, as a conductor for the forceps."—*Med. Chir. Trans. p.* 405.)

Now, when we remember that this gentleman lost only two out of eighty-four patients on whom he operated, his remarks are of great importance; and his cases and the other facts which I have specified, strongly impress my mind with the truth of all that I have urged respecting the advantages of making the opening large, and in the best direction for the easy passage of the stone outwards.

In Mr. Martineau's manner of operating, it is true

he does not make the external wound parallel to that in the bladder, as I venture to recommend, but directs it nearly in a line with the raphe; a circumstance which may, perhaps, account for his continuing the use of the blunt gorget as a conductor for the forceps. Neither is his internal incision carried downwards and outwards, as Bertrandi, Desault, and many other judicious surgeons consider most advantageous. But these defects (if I may presume to call them so) are rendered of less consequence by the rule which Mr. Martineau observes, of *making his first incision long and deep*, and avoiding all stretching and laceration of the parts. Like Langenbeck, he uses a staff, the groove of which is much wider and deeper than usual, and therefore more easily felt. This instrument his assistant holds, in the way preferred by Scarpa, nearly in an upright straight direction. "After the first incision (says Mr. Martineau), I look if the staff is not altered in its situation, and then feeling for the groove, I introduce the point of the knife into it, *as low down as I can, and cut the membranous part of the urethra, continuing my knife through the prostate into the bladder; when, instead of enlarging the wound downwards, and endangering the rectum, I turn the edge of the blade towards the ischium, and make a lateral enlargement of the wound in withdrawing the knife.*"—(See *Med. Chir. Trans. vol.* 11, *p.* 409.) This description is particularly interesting, as coming from a gentleman who had so much experience and success.

With respect to the degree of importance which ought to be attached to the fear of effusion of urine, between the bladder and rectum, gangrene, fistulæ, &c., I can only say, that they are inconveniences which are not commonly observed after lithotomy in this country. In two or three instances only, I have known the urine come through the wound longer than usual, and these cases ended well. As for the extravasation of urine and sloughing, I shall merely remark, that although there cannot be a doubt of their occasional occurrence, they have not taken place after any of the numerous operations, with the results of which I have been acquainted.

All these facts and considerations, therefore, incline me to doubt whether the apprehension of the effusion of urine, fistulæ, &c. be sufficiently serious and well founded to make it advisable for surgeons to relinquish the plan of making a complete division of the side of the prostate gland and neck of the bladder, in the operation of lithotomy. Nor is it at all clear to my mind, that effusion of urine and sloughing are likely to be the effect of practising a free opening. Indeed, whenever they do happen, I believe they proceed from a totally different cause, viz. from the incision in the skin being too small and too high up, and from the axis of the internal part of the incision not corresponding with that of the external wound. Hence the urine does not readily find its way outwards, and some of it passes into the neighbouring cellular membrane.

In confirmation of the foregoing remarks, I beg leave to cite the sentiments of one of the greatest and most experienced of modern surgeons. Speaking of the defects of Hawkins's gorget, Desault observes, "La méthode de l'enforcer horizontalement dans la vessie sur la cathéter tenu à angle droit avec le corps, a deux grands désavantages: d'un côté, celui de pénétrer par l'endroit le plus rétréci du pubis, et par conséquent de ne faire que difficilement une ouverture suffisante; d'un autre côté, celui de ne pas établir de parallélisme entre l'incision extérieure des tégumens qui est oblique et celle du col de la vessie et de la prostate, qui se trouve alors horizontale. Delà la possibilité des infiltrations par les obstacles que les urines trouveront à s'écouler."

No doubt also some of the worst and most dangerous urinary extravasations after lithotomy, have proceeded from another cause, pointed out by the same excellent surgeon. "Imprudemment porté dans la vessie, le gorgeret peut aller, par le stylet beaucoup trop long qui le termine, heurter, déchirer, perforer même la membrane de la vessie, et donner lieu à des infiltrations, d'autant plus dangereuses que le lieu d'où elles partent est plus inaccessible. Cet accident est surtout à craindre, lorsque, comme les Anglais, on se sert de cathéter sans cul-de-sac."—(See *Œuvres Chir. de Desault par Bichat, t.* 2, *p.* 460, 461.)

I regret that the observations published by me, relative to Scarpa's method of performing lithotomy, should not have seemed to him a fair account of the subject, and that he should have deemed it necessary to declare my statement of his incision being too small, and inadequate to the passage of any but calculi under the middling size, manifestly false.—(*Opuscoli di Chirurgia, vol.* 1, *p.* 52.) He supposes that Cheselden, Frère Jacques, and Côme, in their successful operations, made the limited kind of incision which he himself recommends, and did not cut the bladder itself; a position that does not appear to me correct. He asserts, that after the side of the prostate gland is divided, the orifice of the bladder is capable of yielding so as to allow the stone to pass out without danger, if this part of the operation be done slowly and gradually; and he supports his declaration on this point by a reference to the safety with which the orifice of the female bladder is dilated for the extraction of calculi of considerable size: a case hardly presenting an analogy; first, because there is no wound made whatever, and secondly, because lithotomy itself, in women, is a safe measure, compared with what it is in men. The frequent evils of dilating the orifice of the femoral bladder, however, he frankly acknowledges in another part of his writings, and enumerates as the ground of his disapprobation of the practice.—(See *Opuscoli, &c. vol.* 1, *p.* 105.) It does not appear to me that Scarpa's gorget can make the division of the prostate in a direction corresponding to that of the external parts. This view, he thinks, is not founded on correct principles; and he maintains that his incision in the prostate does correspond to the outer wound, because, when the bladder is empty, the prostate is naturally placed in a line sloping from the arch of the pubes to the coccyx, and with its posterior surface resting on the rectum, as is represented in *Camper's Demonst. Anat. Pathol. lib.* 2, *tab.* 3, *fig.* 2. This explanation is not satisfactory to myself; but I have great pleasure in mentioning it, as it has appeared to Scarpa to amount to a refutation of my observation, that his gorget does not make a division of the prostatic portion of the urethra in a direction corresponding to the axis of the wound of the external parts.—(*Opuscoli di Chirurgia, vol.* 1, *p.* 52.)

LITHOTOMY THROUGH THE RECTUM.

This method may be said to have been first suggested in a work published at Bâle, in the 16th century, by an author who assumed the name of Vegetius:—"Jubet per vulnus recti intestini, et vesicæ aculeo lapidem ejicere," says Haller, in speaking of this writer.—(*Bibl. Chir. vol.* 1, *p.* 102.) But the proposal never received much attention until the year 1816, when M. Sanson, in France, gave an account of this manner of operating, and urged several considerations in favour of it. In that country, however, the operation has been performed only by Sanson and Dupuytren, and though the first trial made by the latter proved successful, the other French surgeons do not appear to have imitated him. Dupuytren himself has also now given up the practice. Almost as soon as this method was heard of on the other side of the Alps, it was put to the test of experience by Barbantini, in a case where every other plan of operating appeared hardly practicable. "The connexion of the urethra with the rectum, prostate gland, and posterior part of the bladder (says M. Sanson), made me easily perceive, that by dividing the sphincter ani and some of the rectum near the root of the penis, I should expose not only the apex of the prostate gland, but a more or less considerable portion of this body, and that I should then be able to penetrate into the cavity of the bladder, either at the neck through the prostate, or at its posterior part." It was the latter method which M. Sanson first tried upon the dead subject. The body was placed in the position usually chosen for the common ways of operating, and a staff was introduced and held perpendicularly by an assistant. A bistoury, with its blade kept flat on the left fore-finger, was now introduced into the rectum, and the edge being turned upwards, M. Sanson, with one stroke, in the direction of the raphe, cut the sphincter ani, and the lower part of the rectum. The bottom of the prostate gland being thus exposed, the finger was next passed beyond its solid substance, where the staff was readily perceptible through the thin parietes of the rectum and bladder. While the latter instrument was steadily maintained in its original position, M. Sanson here introduced the knife into the bladder, and, following the groove of the staff, made an incision about an inch in length. At this instant,

the flow of urine from the wound indicated that the bladder had had an opening made in it. On examination, the parts divided were found to be the sphincter, the lower part of the rectum, the back part of the prostate, and the adjacent portion of the bladder. Another mode, contemplated by M. Sanson, was, after dividing the sphincter ani, to cut the termination of the membranous part of the urethra along the groove of the staff held perpendicularly, and by the same guidance to extend the incision in the median line through the prostate gland and neck of the bladder.

In Barbantini's case the calculus was so large that it made a considerable prominence in the rectum, where it was felt extending across from one tuberosity of the ischium to the other. On account of its size, its exraction by the lateral operation was considered impracticable; and as it was not thought advisable or easy to break such a mass, and Barbantini regarded the high operation as more difficult and uncertain in its results than the common method, it was determined to operate through the rectum. The attempt was delayed some days by the impossibility of introducing the staff effectually, which was stopped at its entrance into the bladder by the calculus. But as a grooved instrument was judged to be an essential guide, Barbantini caused a long director to be constructed, which he thought might be passed more conveniently than the staff into the first incision. He also provided himself with long forceps, the blades of which were very broad, and admitted of being put separately over the stone. A staff having been introduced, the operation was done after M. Sanson's manner, except that a wooden gorget was introduced for the protection of the rectum, and the prostate gland was left undivided at the fore part of the wound. When the bladder has been opened at the lower part of the rectum, as far as the groove of the staff served as a guide, the latter instrument was withdrawn, and the long director introduced into the incision, which, under its guidance, was then enlarged to the necessary extent. With some difficulty the stone was then extracted, and found to weigh nine ounces and a half. For about eighteen days the urine passed away by the anus, only a few drops occasionally issuing from the urethra. As this circumstance gave Barbantini some uneasiness, he introduced his finger into the bladder, the inner surface of which, near the wound, he found covered with encysted calculous matter, which was very adherent. At length, however, it was gradually removed, with a portion of new-formed membrane, by attempts repeated with the finger several days in succession. A catheter was then introduced, through which, at first, almost the whole of the urine flowed. But the tube being afterward obstructed with mucus, it became necessary frequently to clear it by injecting tepid water. The cure now seemed to proceed with rapidity. When the feces were hard, none of them passed into the bladder; but when they were liquid, a part of them were voided with the urine through the tube, though without any inconvenience. At the end of fifty days, scarcely any urine passed out of the wound; the patient, therefore, went into the country, where, in the course of another month, the cure was complete.

A few years ago I saw an example, in which a calculus had made its way through the prostatic portion of the urethra, and formed, with the swelling of the soft parts, a considerable prominence within the rectum. If the patient had been under my care, I should certainly have made an incision directly on the tumour just within the sphincter, by which means the calculus might have been removed with great ease, and less risk than dividing the prostate. However, the latter method was followed, and the case had a very favourable termination. In this instance, as the sound, in its passage, only occasionally touched a small point of the calculus which approached the urethra, and this just at the instant before its entrance into the cavity of the bladder, the exact nature of the case was for some time a matter of doubt to several skilful surgeons who were consulted.

Respecting the merits of lithotomy through the rectum, I think the practice well deserving the consideration of the profession, where the calculus is known beforehand to be of unusual size. It must be less painful, I apprehend, than the high operation, and perhaps more easy of execution. Even Scarpa, who decidedly condemns the recto-vesical operation as it is termed, acknowledges that a large calculus may indeed be thus extracted more speedily, and with less risk of injury to important parts, than by the high operation; but, says he, in addition to the consideration that in such cases every mode of operating is contraindicated by the morbid state of the bladder, it is to be recollected, that after the recto-vesical method there is always left an open passage for the feces from the rectum into the bladder, and for the urine from the bladder into the rectum. Of three individuals within his knowledge, who have been operated upon in this manner for very large stones, two died soon afterward of sloughing of the bladder, and the third led for some time a miserable existence, discharging fecal urine, and urine mixed with excrement. Instructed by these disasters, some Italian surgeons, not declared advocates for the new method, very laudably endeavoured to obviate them in future; and having ascertained that for the extraction of a stone of moderate size, such as can be conveniently taken out by the perinæum, it is not at all necessary to open the fundus of the bladder, they adopted Sanson's method, viz. that of cutting the sphincter ani from below upwards, and then to lay open vertically, from above downwards, the membranous part of the urethra and the prostate gland, so as to let the knife meet the first wound in the sphincter. "In fact (says Scarpa), they really attained the object, namely, that of hindering the feces from entering the bladder after the extraction of the stone. This was, no doubt, of great importance in their operation, yet, as it seems to me, not a consideration that ought to make the recto-vesical preferable to the lateral operation whenever the stone can be taken out through the perinæum; first, because the vertical section of the membranous part of the urethra and the prostate gland cannot be executed without separating the left seminal duct, and sometimes the right one, from the vas deferens and vesicula seminalis of the same side; secondly, because the wound is still exposed to the contact of the feces."—(*Sul Taglio Retto-Vesicale, p.* 4. Also *Opuscoli di Chirurgia, vol.* 1, *p.* 69.) In reply to Vacca's observations he urges also against the recto-vesical operation, when the wound must be made extensive enough for the removal of a large calculus, the risk there is of wounding the fold of the peritoneum, which, if the bladder is thickened and contracted, descends lower than is generally supposed.—(*P.* 36.) This accident really happened in one case which was dissected by Geri of Turin.—(*Repert. Med. Chir. de Torino, No.* 18.)

Here we discern a strong reason against Mr. Sleigh's modification of the operation, in addition to the probability of an incurable communication between the rectum and the bladder, as sufficiently proved in the history of the recto-vesical operation.—(See *Scarpa's Opuscoli, vol.* 1.) The part of the bladder which Mr. Sleigh proposes to divide is bounded laterally by the vasa deferentia and vesiculæ seminales; superiorly by the *cul-de-sac* of the peritoneum; and inferiorly by the prostate gland, and the union of the seminal tubes. The chief peculiarity in the plan is that of not dividing the sphincter ani and the prostate gland. Cutting the first part, he conceives, perhaps without sufficient foundation, must seriously increase the patient's sufferings, while dividing the prostate gland vertically cannot be done without injuring one of the seminal ducts; a point on which he is more correct, and in agreement with Scarpa. In endeavouring to avoid this danger, however, he runs into a still more formidable one, viz. that of wounding the *cul-de-sac* of the peritoneum, and exciting fatal inflammation within the abdomen.—(See *Sleigh's Essay on an improved Method of Cutting for Urinary Calculi; or the Posterior Operation of Lithotomy; 8vo. Lond.* 1824.)

Even when the stone is of extraordinary magnitude, it may be doubted whether the recto-vesical method ought to be preferred either to the high or the lateral operation; by which last, stones of larger size than that extracted by Barbantini have been successfully taken out by Sir A. Cooper, Mr. Mayo of Winchester, Dr. Klein of Stuttgard, and others. The most serious consideration is, whether a large incision, forming a communication between the bladder and rectum, will generally heal up, as well or even more favourably than in Barbantini's case. A smaller wound in the same part, it appears, may be soon cured; for in the instance reported by Sanson, the boy was quite well on the twentieth day. On this point, it must be confessed, modern

reports are becoming extremely unfavourable. Of seven patients, operated upon with division of the fundus of the bladder (says Professor Vacca), four were left with a recto-vesical fistula, and the fifth was in danger of one. In four cases operated upon, Professor Geri knew of three such terminations. Besides these facts, observes Scarpa, of which I could increase the number by others within my knowledge, it is to be taken into the account, that in some individuals the fecal and urinary fistula, after seeming to be closed for some time, has opened again.—(*Sul Taglio Retto-Vesicale, p.* 40.) In the School of Practical Surgery at Turin, out of five operated upon through the rectum, three died, although eleven other patients cut in the lateral way all recovered in a short time. Only one had rather severe symptoms, which were ascribed to a wound of the rectum. Dupuytren, who tried the recto-vesical operation in six instances, as performed by Vacca, lost three of his patients of inflammation within the pelvis. The first patient died a fortnight after the operation; and two on the third day. The three others remained with incurable fistulæ, through which the urine either continually dribbled, or was partially expelled when the bladder contracted.—(See *M. Louis Senn, Parallèle de la Taille, Paris*, 1824; *Scarpa, Opuscoli di Chirurgia, vol.* 1, *p.* 135.) Dupuytren, on being asked one day if he would still try the plan, made no answer, but shook his head. Barbantini, who first put the operation to the test of experience in Italy, has, after farther trials of it, and the mature consideration of Scarpa's objections to it, candidly acknowledged its great disadvantages in comparison with the lateral operation.—(See *Scarpa's Opuscoli di Chirurgia, vol.* 1, *p.* 100.) Riberi also saw two children cut by Sanson at Paris; one died a few days afterward of peritonitis; and the other was given up before his departure from that city.—(*Ragguaglio di tredici Cistotomie, Torino*, 1822; *and Scarpa sul Taglio Retto-Vesicale, p.* 55.) *Sanson, Des Moyens de Parvenir à la Vessie par le Rectum*, 4*to. Paris*, 1817; *N. Barbantini, Obs. relative à l'Extraction d'un Calcul Urinaire très volumineux, operée au moyen de la Taille Vesico-Rectale*, 8*vo. Lucques*, 1819; *Journ. LITHOTOMY IN WOMEN.

Women suffer less from the stone than men, and far less frequently stand in need of lithotomy. It is not, however, that their urine will not so readily produce the concretions which are termed urinary calculi. The reason is altogether owing to the shortness, largeness, and very dilatable nature of the female urethra; circumstances which in general render the expulsion of the stone with the urine almost a matter of certainty. The records of surgery present us with numerous instances where calculi of vast size have been spontaneously voided through the meatus urinarius, either suddenly without pain, or after more or less time and suffering. Heister mentions several well authenticated examples. Middleton has also related a case, where a stone, weighing four ounces, was expelled in a fit of coughing, after lodging in the passage a week. Colot speaks of another instance, where a stone about as large as a goose's egg, after lying in the meatus urinarius seven or eight days, and causing a retention of urine, was voided in a paroxysm of pain. A remarkable case is related by Dr. Molineux in the early part of the *Philosophical Transactions;* a woman voided a stone, the circumference of which measured the longest way seven inches and six-tenths, and round about, where it was thickest, five inches and three-quarters; its weight being near two ounces and a half troy. And Dr. Yelloly has related an interesting example, in which a calculus weighing three ounces three and a half drachms troy, and lodged in the meatus urinarius, was easily taken out with the fingers.—(See *Med. Chir. Trans. vol.* 6, *p.* 577.) Dr. Yelloly also refers to several very remarkable instances, described in the *Phil. Trans. vols.* 12, 15, 17, 20, 34, 42, and 55, proving what large stones will pass out of the female urethra, either spontaneously or with the aid of dilatation and manual assistance. Were any doubts now left of this fact, they would be immediately removed by other histories, especially those contained in the papers published by Sir A. Cooper.—(See *Med. Chir. Trans. vols.* 8 *and* 12.)

Sometimes, after the passage of large calculi, the patient has been afflicted with an incontinence of urine; but, in general, this grievance lasts only a short time.

The occasional spontaneous discharge of very large calculi through the meatus urinarius, led Frederic de Leauson to deliver the advice not to interfere with them, as he thought they would all present themselves sooner or later at the orifice of that passage, and admit of being taken away with the fingers.—(See *Traité Nouveau pour aisément parvenir à la Vraie Curation de plusieurs belles Opérations, &c. Génève*, 1674.)

When surgeons began to consider what very large calculi were sometimes spontaneously voided, and the large size and dilatable nature of the female urethra, they suspected that it would be a good practice to dilate this passage by mechanical contrivances, until it would allow the stone to be extracted, and thus all occasion for cutting instruments might be superseded. With this view, Tolet first proposed suddenly dilating the passage with two steel instruments, called a male and female conductor, between which the fingers or forceps were passed for the removal of the calculus.—(*Traité de la Lithotomie, Paris*, 1681.) But as it was afterward rightly judged, that the dilatation would produce less suffering and injury, if more gradually effected, Douglas suggested the practice of dilating the meatus urinarius with sponge or dried gentian root.

Mr. Bromfield published the case of a young girl, in whom he effected the necessary dilatation by introducing into the meatus urinarius the appendicula cœci of a small animal in a collapsed state, and then filling it with water, by means of a syringe; thus furnishing a hint for the construction of instruments on the principle of Mr. Arnott's dilator. The piece of gut thus distended was drawn out in proportion as the cervix vesicæ opened, and, in a few hours, the dilatation was so far accomplished, that the calculus had room to pass out.—(See *Chir. Obs. and Cases, vol.* 2, *p.* 276.)

Mr. Thomas met with a case in which, after dilating the meatus urinarius with a sponge tent, he succeeded in extracting an earpicker which lay across the neck of the bladder. The passage was so much enlarged, that the left fore-finger was most easily introduced, and (says this gentleman), "I believe had the case required it, both thumb and finger would have passed into the bladder without the smallest difficulty." After adverting to this and other facts, proving the ease with which the female urethra can be dilated, Mr. Thomas remarks: "If these relations can be credited, and there is no reason why they should not, I can hardly conceive any case in a young and healthy female subject, and where the bladder is free from disease, where a very large stone may not be extracted, without the use of any other instrument than the forceps, the urethra having first been sufficiently dilated by means of the sponge tents. For this purpose, the blades of the forceps need not be so thick and strong as those commonly employed."—(See *Med. Chir. Trans. vol.* 1, *p.* 123—129.) Many facts of a similar kind are on record, and one, in which a large needle-case was extracted, is referred to in a modern periodical work.—(See *Quarterly Journ. of Foreign Med. vol.* 2, *p.* 331.)

Some surgeons have extracted stones from the female bladder in the following manner: the patient having been placed in the position commonly adopted in the lateral operation, a straight staff, with a blunt end, is introduced into the bladder through the meatus urinarius. The surgeon then passes along the groove of the instrument the beak of a blunt gorget, which instrument becoming wider towards the handle, effects a part of the necessary dilatation. The staff being withdrawn, and the handle of the gorget taken hold of with the left hand, the right fore-finger, with the nail turned downwards, is now introduced slowly along the concavity of the instrument. When the urethra and neck of the bladder have thus been sufficiently dilated, the finger is withdrawn, and a small pair of forceps passed into the bladder. The gorget is now removed, and the stone taken hold of and extracted.—(*Sabatier, Médecine Opératoire, t.* 2, *p.* 103.)

This plan, however, has been objected to on account of the dilatation being too suddenly effected; and the practice of gradually expanding the meatus urinarius

with the sponge tent preferred. The retention of urine during the continuance of the sponge, certainly causes great irritation; and if this method be followed, therefore, I consider Mr. C. Hutchison's suggestion of placing a catheter in its centre, as mentioned by Sir A. Cooper, worthy of attention.—(See *Med. Chir. Trans. vol.* 8, *p.* 433.)

Sir A. Cooper, who is an advocate for the practice of removing calculi from the female bladder by dilating the meatus urinarius, now employs for this purpose "an instrument constructed upon the principle of the speculum ani and speculum oris," and which has the advantage of permitting the urine to escape, while it dilates the passage sufficiently for the entrance of the forceps, and the removal of a stone of considerable dimensions. He believes that, "if the stone be small, the dilatation should be accomplished in a few minutes; but that if it be large, it will be better to dilate but little, from day to day, until the greatest degree of extension is accomplished; carefully avoiding contusion, which is much to be dreaded."—(See *Med. Chir. Trans. vol.* 12, *p.* 240.)

Notwithstanding these favourable accounts of the practice of dilating the female urethra, for the purpose of removing calculi from the bladder, there are very good surgeons who deem an incision the best practice. It is certain that some patients have found the method insufferably tedious and painful. But the strongest objection is the incontinence of urine, which occasionally follows a great distention of the urethra and neck of the bladder. Klein, one of the most experienced operative surgeons in Germany, states that he has tried both plans, and that the use of the knife is much less frequently followed by incontinence of urine. And Scarpa declares, that when the calculus is large, and not soft and fragile, the method of extracting it by dilatation is almost always followed by incontinence of urine.—(*Sul Taglio Retto-Vesicale*, *p.* 49.) On the other hand, Mr. Thomas believes, that this unpleasant symptom is quite as often a consequence of the operation of lithotomy, as now usually performed (*Med. Chir. Trans. vol.* 1, *p.* 127); and Sir A. Cooper expressly states, that the greatest advantage of his mode of extracting calculi with a dilating instrument, is the preservation of the power of retaining the urine.—(See *Med. Chir. Trans. vol.* 12, *p.* 240.) Of the propriety of removing calculi under a certain size, and also pieces of broken catheter, &c., in this manner, no doubt can be entertained; but if the foreign body were very large, I should consider an incision the safest and least painful practice.

In females, lithotomy is much more easy of execution, and less dangerous, than in male subjects. It may be done in various ways; but the surgeons of the present time constantly follow the mode of making the requisite opening by dividing the urethra and neck of the bladder. Louis employed for this purpose a knife, which cut on each side, and was contained in a sheath; Le Blanc, a concealed bistoury, which had only one cutting edge; Le Cat, his gorgeret-cystotome; Frère Côme, his lithotome caché. Of these instruments, the best I think is that of Frère Côme. But, at present, every surgeon knows that the operation may be done as conveniently as possible with a common director, and a knife that has a long, narrow, straight blade. A straight staff, or director, is introduced through the meatus urinarius; the groove is turned obliquely downwards and outwards, in a direction parallel to the ramus of the left os pubis; and the knife is thus conducted into the bladder, and makes the necessary incision through the whole extent of the passage and neck of the bladder.

Louis and Fleurant, as I have said, were the inventors of particular bistouries for dividing both sides of the female urethra at once. The instrument of the former effected this purpose in passing from without inwards; that of the latter, in passing from within outwards. Fleurant's bistoury bears some resemblance in principle to Frère Côme's lithotome caché, or to the cutting forceps with which Franco divided the neck of the bladder. The reason assigned as a recommendation of these bistouries is, that they serve to make a freer opening for the passage of large stones than can be safely made by cutting only in one direction. When the calculus is large, it is certainly difficult to procure a free opening without cutting the vagina, in front of which passage there is but little space under the pubes for the removal of the stone. Hence, Dubois invented a new method, which consists in dividing the meatus urinarius directly upwards towards the symphysis of the pubes, dilating the wound, and keeping the vagina out of the way by means of a blunt gorget, and then taking out the calculus with the forceps. This plan is acknowledged to be very painful, yet generally successful, and not followed by any serious symptoms or incontinence of urine.—(See *Dict. des Sciences Méd. t.* 28, *p.* 436.) Lisfranc also carries the incision upwards, and a little to one side of the symphysis of the pubes, because this mode of operating is found to be less frequently followed by retention of urine. When the opening thus made is not large enough, he makes another cut obliquely downwards and outwards. When the stone is known to be very large, Sabatier and some other modern surgeons prefer the apparatus altus.

[The very powerful objections having been stated to the dilatation of the female urethra by either of the methods proposed, and the fact being admitted that the operations here described are so frequently followed by incontinence of urine and other unpleasant results, it is surprising that Mr. Cooper has not mentioned the operation of M. Dubois, which is not only free from these objections, but entirely void of danger. Having witnessed its success, I esteem it as one of the most important improvements ever made on this interesting subject.

This operation is to be performed thus: the surgeon introduces a *director* through the meatus urinarius into the bladder, with the *groove* directly upwards. An incision is then made directly upwards by the straight bistoury towards the symphysis, extending through the whole course of the urethra, and the neck of the bladder, after which the calculus may be readily extracted by a pair of forceps guided by the left index finger in the same manner as in the lateral operation. One advantage of no small importance is, that in this operation the surgeon needs no assistant, and patients will submit to the operation much earlier, when their native delicacy would otherwise revolt at exposure.—*Reese.*]

A case may present itself in which the posterior part of the bladder, drawn downwards by the weight of the stone, may displace a portion of the vagina, and make it protrude at the vulva in the form of a swelling. Here there would be no doubt of the propriety of cutting into the tumour, and taking out the foreign body contained in it. Rousset performed such an operation, and Fabricius Hildanus, in a case where the stone had partly made its way into the vagina, enlarged the opening, and successfully extracted the foreign body.

Mery proposed to cut into the posterior part of the bladder, through the vagina, after introducing a common curved staff; but the apprehension of urinary fistulæ made him abandon the project.

Extraordinary circumstances may always render a deviation from the common modes of operating not only justifiable, but absolutely necessary. Thus, Tolet met with a case, where a woman had a prolapsus of the uterus, with which the bladder was also displaced. In the latter viscus, several calculi were felt: an incision was made into it, and the stones extracted; after which operation, the displaced parts were reduced, and a speedy cure followed.—(*Sabatier, Médecine Opératoire, t.* 2, *p.* 107.)

The incontinence of urine, consequent to lithotomy in women, is by no means an unfrequent occurrence. Mr. Hey cut two female patients for the stone, both of whom were afterward unable to retain their urine, and were not quite well when discharged from the Leeds Infirmary. These cases led him in a third example to endeavour to prevent the evil by introducing into the vagina a cylindrical linen tent, two inches long and one broad, with a view of bringing the edges of the incision together without obstructing the passage of urine through the urethra. The plan answered, if it be allowable to make such an inference from a single trial. —(See *Hey's Practical Obs. in Surgery*, *p.* 560, *ed.* 1810.)

TREATMENT AFTER THE OPERATION.

If the internal pudendal artery should be wounded and bleed profusely, the best plan is, if possible, first to take out the stone, and then introduce into the wound a piece of firm sponge, with a large cannula passed

through its centre. The expanding property of the sponge, on its becoming wet, will make the necessary degree of compression of the vessel, which lies too deeply to be tied. Linen, wet with cold water, should at the same time be applied to the perinæum and hypogastric region.

I cannot say that it has fallen to my lot to see any cases (out of the great number which I have seen) in which death could be imputed to hemorrhage, notwithstanding the bleeding has often been so profuse, and from so deep a source, just after the operation, as to create suspicion that it proceeded from the internal pudendal artery. Such hemorrhage generally stopped before the patient was put to bed.

[The internal pudendal artery was tied by Dr. Physick, after its being wounded in lithotomy, nearly 30 years since.—*Reese.*]

The majority of patients who die after lithotomy, perish of peritoneal inflammation. Hence, on the least occurrence of tenderness over the abdomen, copious venesection should be put in practice. At the same time, eight or ten leeches should be applied to the hypogastric region. The belly should be fomented, and the bowels kept open with the oleum ricini. The feebleness of the pulse should not deter the practitioner from using the lancet: this symptom is only fallacious, and generally attendant on all inflammation within the abdomen. It is a curious fact, that Mr. Martineau, who lost only two out of 84 patients whom he operated upon for the stone, should *never* have found it requisite to bleed; but it appears to me, that it is a much better argument in favour of the superior safety of operating with the knife and making a free opening, than a reason for discouraging venesection, when inflammation of the peritoneum has come on, which, however, may not be this gentleman's meaning, as he says, "I believe it will be found in adults, that death follows oftener from exhaustion, after a tedious operation, or from despondency, &c. than from acute disease" (*Med. Chir. Trans. vol.* 11, *p.* 412); a sentiment which, I am sure, this gentleman would not have entertained had he been present with me at the opening of the many unfortunate cases which used formerly to occur in the practice with badly made gorgets in St. Bartholomew's Hospital. Together with the above measures, the warm bath, a blister on the lower part of the abdomen, and emollient clysters, are highly proper. I have seen several old subjects die of the irritation of a diseased thickened bladder, continuing after the stone was extracted. They had not the acute symptoms, the inflammatory fever, the general tenderness and tension of the abdomen, as in cases of peritonitis; but they referred their uneasiness to the lower part of the pelvis; and instead of dying in the course of two or three days, as those usually do who perish of peritoneal inflammation, they, for the most part, lingered for two or three weeks after the operation. In these cases, opiate clysters, and blistering the hypogastric region, are the best measures. In some instances of this kind, abscesses form about the neck of the bladder.

[The following communication on this prolific subject is from Professor Jameson of Baltimore. As it contains a brief notice of the comparative merits of lithontrity and the lateral operation, and suggests many practical hints deduced from his extensive experience, I have been unwilling to curtail it (though its length exceeds the limits assigned me by the publishers); and have therefore concluded to insert it entire, in order that the points of difference between him and his predecessors or contemporaries may be fairly stated in his own language. It will be found to possess a simplicity and artlessness, which will make it acceptable to younger surgeons, since these characteristics are too seldom found in the descriptions of this operation by surgical writers. Having witnessed a number of Dr. J.'s operations when I resided in Baltimore, I have been both surprised and pleased at his successful efforts in producing "union by the first intention" in surgical wounds, as well in this, as in other operations. The periodicals of the day have recorded many of his valuable contributions to this department of surgical knowledge, to some of which posterity will award him the merit of originality.

"It may be recollected, that so flattering were the reports from France respecting the operation of lithontrity, in the hands of M. Civiale, that, in the year 1824-5, some of the most distinguished surgeons of America attempted its performance; in all which attempts there were complete failures: nor did the avidity with which this operation was received by operating surgeons remain within the sphere of their action; on the contrary, some of the highly respectable medical journals of this country seemed to vie with each other which was entitled to the meed of praise for having first announced the important intelligence associated with this operation.

Anxious as we always have been to investigate every thing wearing the appearance of improvement, and influenced as we always have been by feelings of humanity in our researches, we did not lose any time in extending our inquiries into the history, character, and merits of the operation of lithontrity. Our investigations resulted in a publication in the late Medical Recorder of Philadelphia, in which we endeavoured to show the inapplicability of the new operation, under so many circumstances, as to come to the conclusion, that the advantages of lithontrity were greatly overrated; and would never, as a general rule of practice, supersede the lateral operation. From that time to the present, we have endeavoured, free from prejudice, to keep pace with the presumed improvements in lithontrity, and we are compelled to say, that we have seen nothing calculated to change former opinions.

One thing we think will be conceded on all hands; that lithontrity will never do away the necessity for the *lateral operation*. And as it has been our lot to differ with a large proportion of the profession, respecting the merits of the new operation, so has it also been our lot to differ essentially with all authorities which have come within our observation, as to the plan of operation, both in the male and female patient.

The limits assigned us will not admit of our instituting any minute investigation, nor of entering generally into the merits or demerits of the several operations; we shall therefore proceed to offer our own experience, and leave the reader to appreciate as to him may seem proper. We will only say farther, that it is our ambition to write for posterity; and, aware as we are of the fleeting character which has so much beset medical science from its dawn, we are not disposed, lightly, to place ourselves in the list of rash speculatists.

Believing, as we do, that we have materially improved the operation of lithotomy in both sexes we purpose laying our views before the public: we will as briefly as possible describe our method. In doing this, we may have occasion to notice some facts connected with the history of this operation.

We need not go far back into the records of surgery, to see the profession altogether ignorant of healing wounds by the *first intention*. This applies more particularly to surgical wounds. Among the greater operations, amputation was the first to claim attention, in respect to saving skin, and thus facilitate the cure of stumps; next, we notice similar attempts to expedite the cure of wounds made in the amputation of the female mamma; then attention was called to a similar plan of procedure in wounds, surgical or others, of the scalp: nor was this important method of healing by the *first intention* neglected in the treatment of wounds generally that seemed rationally to admit of it; but by some strange fatality, it so happened that no one thought of employing this salutary practice in the wound made in operating for the stone, till it fell to us to test this method, and to realize therein our most sanguine expectations.

We have been in the habit of performing this operation, after our own method, for six or seven years: and our success has been such as to make us extremely desirous to acquaint the profession with our plan, and sustain it with two or three cases, by way of illustrating our method of procedure, and of showing the superiority of that method.

So far as we recollect, the better authorities on surgery advise free external incisions, not only for the purpose of gaining easy access to the bladder, but also with a view of obtaining a free outlet for the urine, which is expected to flow through the wound. We are directed by many to carry our incision an inch and a half posterior to the anus, or down to the tuber ischii.

We are decidedly of the opinion that this procedure is attended with several disadvantages; and affords

nothing salutary. The following are some of the objections to this method of operation.

1st. By cutting so far back, we cut deep into the mass of cellular and fatty structures, which fill up the deep space between the tuber ischii, the urethra, and the rectum; this creates an unnecessary extent of wound; and greatly increases the risk of wounding the rectum, while it also lessens the chances of healing the wound *by* the first intention.

2d. As it is our object to heal by the first intention, this is a matter of primary importance. And we know, from repeated observation, that there is no advantage as regards the extraction of the stone in dividing this fatty structure: it is the muscles which form the resistance to extraction.

The following is our plan of procedure in the male subject. The existence of stone ascertained by the sound, and our patient in as good health as we can reasonably expect him to be, we introduce the usual curved staff, grooved on its right side.

The patient is now to be tied; this securely done; while an assistant surgeon holds the staff firmly, the surgeon spreading his hand over the perineum, by placing his thumb on one side of the raphæ, and his fingers of the left hand on the other, he commences his incision about half an inch from the raphæ, left side; and at a point about two inches in advance of the anus in the adult, and about an inch and a quarter in a boy of five or six years, and terminates it opposite the *centre of the anus:* two or three strokes of the scalpel will enable him to divide the muscles of the perineum; and he may now observe, that by dividing the ligamentous union of the several muscles, just behind the bulb of the urethra, that the parts are sufficiently dilated or relaxed. Feeling now for the groove of the staff, which the assistant holds a little turned to the right side of the patient, so as to bring the groove between the lateral and lower aspects of the wound, he pushes the point of the same scalpel through the urethra, *just behind the bulb;* then taking the staff in his left hand, he turns its convex side to the inferior aspect of the wound, ascertains that the end of the staff is well *home* in the bladder. This arranged, he now slowly passes the scalpel along the groove of the staff, till he perceives a gush of urine, or till he feels that the knife meets no farther resistance.

Before withdrawing the staff, the surgeon should pass in his finger to ascertain that the wound is sufficiently large; and to ascertain, as nearly as may be, the size of the calculus. This done, provided the calculus is of such size as to admit of removal without risk of bruising the parts, Barton's forceps are to be introduced; and the stone removed in the most gentle manner, both with a view of avoiding bruising the parts, and of avoiding the breaking off of fragments of the stone. Should any be broken off, after removing whatever number of calculi may be present, and larger fragments, the smaller particles may be readily washed out with warm water, by means of a syringe.

The operation thus completed, we pass a pretty large flexible catheter; in a boy of five or six years of age, about the size of the ordinary silver catheter; in men, about the size of the female catheter. This will be most easily introduced by putting into the tube a stylet, having the usual curve of the silver catheter. The tube must be tied by means of a small soft strip of rag to the penis.

The patient, being untied, is laid on his right side; his knees brought together, and tied by means of a silk handkerchief, or other soft bandage. No sutures will be necessary; but it is absolutely essential that the patient lie quietly on his side for two or three days, so as to obtain the effect of a syphon from the tube. He may, however, after some hours, if particularly desirous, turn upon his left side, never forgetting, however, that the outer end of the tube must be lower than the inner. The patient may be kept comfortably dry, by using a cup or large sponge to contain the water, as it drops from the tube.

We shall now state a few cases, and conclude our observations with a recapitulation of some of the more important steps of our operation.

These cases are selected from others equally successful; but we have no disposition to conceal the fact, that in some instances we have not succeeded so well; of the latter we shall presently take some notice.

A boy aged about eight years had suffered several years with stone; his aspect was sickly; his sufferings extreme; and his growth much retarded; mostly incapacitated for going to school.

The necessary wound was made agreeably to our method, the forceps introduced, and two calculi, of the size of the largest filbert, caught in the chops of the instrument at once. The tube was introduced, &c. &c.

There were no constitutional symptoms; on the contrary, the patient was calm and cheerful, after the shock of the operation passed over, which took place in a few hours; of course there was no constitutional treatment, except the enforcement of a low diet. The wound was neither painful, red, heated, or swelled at any period; on the contrary, it closed the first night, and continued so, not affording any discharge whatever; no dressing was applied, except washing the parts once a day with cold water. On the eighth day after the operation, we met him in full dress at the street door; and the next day found him playing tricks with his brother, at the hydrant in the yard.

In the last month (March, 1830), we operated on a lad, between six and seven years of age, who had suffered severely for about eighteen months with stone; and who came from an aguish neighbourhood, on the eastern shore of this state.

Nothing remarkable occurred in the operation, except an unusual amount of hemorrhage. This proceeded however, from the vessels of the perineum, and ceased as soon as the operation was over. On the day succeeding the operation, he was so well as to play with the children of the house in which he lay, and his attendants, though extremely kind and attentive, forgot themselves, and suffered the patient to turn on his back, till the water accumulated in the bladder, and caused him to pass it off, part of which escaped through the wound. I felt much concerned, and apprehensive that this would interrupt the healing of the wound by the first intention; in this, however, I was agreeably disappointed; the healing of the wound progressed very kindly, although there was a slight purulent discharge from the outer part of the wound, and a little tumefaction and tenderness. No interruption farther took place; the tube performed its office well; the patient took one dose of castor oil to remove a constipated state of the bowels, and had not one unpleasant symptom. Day after day as we inquired how he was, he answered that he was "better."

On the eighth day we placed our little patient upon a chair; on the ninth we found him in full dress on the pavement, at play in the street. Indeed, it would not have been essential whether we had seen him after the operation, as there was no occasion for attention on our part, except by way of precaution.

We operated upon a very respectable member of our profession from the state of Virginia, in 1827. We extracted through the wound we usually make, a stone about the size of a very large nipple glass, being circular, but flat shaped; a good deal like the nipple glass, but thicker. A shape so unfavourable induced us at once to break the stone; this done, the fragments were removed in a few minutes, by means of the forceps, scoops, and the syringe.

A tube was introduced and left in the bladder as usual after our operation for the stone. The patient got on very well till the fourth or fifth day; we believed the wound to be pretty well healed, being free from pain, swelling, or inflammation; nor was there any uneasiness or leakage whatever through the wound. The patient was an invalid from disease of the spine, and could not lie comfortably on his side, which is essential, that the outer end of the tube may be kept lower than that within the bladder, so that the water may pass off guttatim.

The patient became impatient, and begged for permission to lie on his back; this, on account of his not being able to lie comfortably on his side, was granted occasionally through the day, suffering him to turn upon his back for half an hour, and sometimes perhaps longer; when he was again turned on his side, and the water suffered to run out of the tube before the bladder acted to expel it.

He became anxious to sleep on his back, and assured me his sleep was habitually so imperfect, and his kind relatives who were with him were so vigilant, that he could certainly turn every hour; under such circumstances he was indulged. It turned out that he slept soundly, and his friends, who for many long months

had never left him an hour alone, happened to fall asleep. The patient slept about two hours, awoke with a desire to pass water, the bladder contracted spasmodically, and the tube not affording sufficient outlet, forced the water through the wound.

The escape of water in this way was no doubt facilitated by the languid and feeble state of the parts involved in the wound. Had there been more vigour of constitution and of the parts involved in the paralysis from the spinal disease, the union would have been too firm in this time to yield to the force of the bladder upon the urine. The water under more favourable circumstances would have passed along the outside of the tube as we have sometimes seen, after the tube was worn for a considerable time.

The parts were well cleansed from the urine, and the lips of the wound, which did not now exceed three-fourths of an inch in length, being pressed gently together with the thumb and fore-finger, a small oblong *concave pad* was put on and bound on pretty firmly, by tapes pressing up before and behind, to be fastened to a bandage around the body. This pad had the effect of holding the lips of the wound together, and thus facilitated its closure. The tube being replaced, and kept running, the wound very soon healed up without the employment of any other means for that purpose, notwithstanding there was a little weeping of urine at times, attention merely being paid to keeping the part perfectly clean, by applying occasionally a compress of dry rag under the *pad*.

When we look at the whole aspect of this case we must see, that there was great risk of fistula in perineo; but this unpleasant occurrence was prevented by the simple contrivance we have mentioned, aided by the precaution of not letting the bladder fill with water, but by means of the tube conveying it away as fast as it descended into the bladder.

We shall now recapitulate some of the more important points connected with the operation of lithotomy.

1. Let the external incision be of moderate extent, and terminate opposite the centre of the anus.

2. Let the incision in the adult be about two inches; never exceeding two and a half in length; its course directly parallel with the *raphe* of the perinæum.

3. The central point of union of the perineal muscles being divided, when attached to the ligamentous point of the triangular ligament, will afford room enough for the forceps.

4. If the patient is properly secured, and the knees kept wide apart, the incision will gape open and the staff will be quite easily distinguished by feeling with the left fore-finger; with this finger on the instrument enter the point of a scalpel into the groove; then keeping the knife steadily in the groove, take hold of the handle of the staff with the left hand, then pass the knife slowly and steadily, until the necessary wound is made in the neck of the bladder, which, as nearly as we can measure, should never pass beyond the base of the prostate gland.

5. The cutting edge of the scalpel should not exceed an inch, or an inch and a quarter; this will prevent us from wounding external parts while we are cutting within, and thus prevent all risk of wounding the internal pudic artery. The most favourable division of the prostate, and other parts, will be made by holding the knife laterally, midway between the horizontal and perpendicular lines, which may be imagined as passing through the middle of the prostate gland.

6. In introducing the tube into the bladder, let the end of it be slipped on a finger passed into the wound, and so placed at the neck of the bladder, as to ascertain by it how far the tube passes into the bladder; it may, however, be passed on gently till the end reaches the fundus of the bladder. If it is properly placed, and the patient put upon his right side, the urine will soon commence dropping from the tube; this assures us that all is right.

7. If the wound in the neck of the bladder is large enough to admit the forceps easily, it is sufficiently large; and if the stone be too large for extraction, it should be broken; for which purpose, in most cases, we may use common strong lithotomy forceps. When the size of the stone is enormous, the forceps which we contrived for the purpose of breaking such calculi, should be used. By introducing the blades of these separately, we can easily grasp a stone of any size through the ordinary wound, and drill the mass to pieces.

8. In the selection of a tube, we should choose those that are most flexible, having regard, however, to their being sufficiently thick in their structure, so as not to collapse. The eyes should be large, and their edges as smooth as possible. The common gum elastic catheters of the shops, when of good quality, answer very well. Never pass the tube into the bladder without having a stylet in it, and it will be best to have it fill the caliber of the tube.

9. We have always found a soft string tied to the outer end of the tube, and carried back and tied around the root of the penis, to answer very well for confining the tube in its place. The penis will generally become somewhat swelled in a few hours, and the string must be loosened should it become too tight.

10. Should it happen that the water does not drop well from the tube, some warm water may be very gently passed into the bladder through the tube, and drawn out again by means of a penis syringe. Or, sometimes passing in a very limber wire to the eyes of the tube, and thereby removing some clot of blood, or mucus, will answer. Should all this fail, withdraw the tube, and introduce another.

11. It will sometimes happen, that owing to careless ness of nurses, or inattention of patients, the precaution of lying on the side is neglected; the water accumulates in the bladder; and when the bladder is stimulated into action, the wound is forced open by the urine. We have seen, by the facts already stated, that if this does not advance too far before we are aware of the occurrence, we may so manage the affair as to heal up the wound sooner than by the ordinary method.

12. It has happened once, that a tube which we passed became kinked, as the mechanics call it, which is a breaking in of one side so as to close the caliber of the tube. In this case we were foiled in our attempt to heal the wound by the first intention; but no evil arose from the accident. It has also happened, perhaps twice, that the tube became clogged at the *eyes*, and would not convey off the urine. With boys it will be almost impossible to renew the tube. Should we be disappointed, which will seldom happen if we conduct the operation well, we should withdraw the tube: in the adult we should insist on its removal. The operation of replacing the tube is more frightful than painful; it cannot therefore be so well performed upon small boys.

13. The tube should not be left in more than a week without examination: in some cases a calcareous crust will form in a few days; and if there be such a predisposition, there might be some risk of forming a *nucleus*. In most instances, however, the tube might be worn a long time without the formation of any such concrete.

Lastly, to obtain the advantages of this operation it must be correctly understood: where it is conducted in a careless manner, without due attention to the several points which we have suggested, success cannot be expected."

By the note I have appended to the article of Lithotomy on the Female, p. 156, it will be found that Dr. J.'s operation is the same as that practised by M. Dubois. The question of originality I cannot decide, not being in possession of the dates in which it was performed by the two surgeons.

OPERATION OF LITHOTOMY ON THE FEMALE

"It is well known that considerable difficulties have attended this operation on the female, arising principally from the circumstance of incontinence almost necessarily succeeding every method of operation which has been practised, whether by passing a gorget directly along the urethra and cutting the membranous structure, on the upper side of the vagina; by direct or immediate dilatation by means of instruments; or dilatation by means of the sponge tent.

M. Lisfranc, it will be recollected, has proposed and practised a new method within the last few years, contrived with the view of obviating this truly lamentable misfortune to the female; we mean incontinence. We have carefully examined the operation as described by that author. We think it much superior to any of the methods formerly practised, but we nevertheless

think it is unnecessarily severe and complex; and although ingeniously contrived, it is inferior to a method which we have employed twice, much to our satisfaction. This operation was announced in the late Medical Recorder; and when last in Philadelphia, a very respectable member of the profession informed us, that our friend Doctor Physick had once performed it to his entire satisfaction.

Every man acquainted with disease of the bladder in the female must be aware, that they are disposed, in most instances, to conceal such disease, till they experience very great sufferings. In this way, the bladder and urethra are rendered so exquisitely sensible to the touch, that the use of the sound, sponge tent, &c. is attended with severe pain.

At first sight it might be supposed that the operation of Civialé would succeed well in the female; and probably in some cases it may succeed very well: it will not always, as we know, in a case of encysted stone; and I am inclined to believe that, in most cases, we shall be enabled more easily to relieve females by the operation we are about to describe, than by lithontrity. We believe that any advantage which may grow out of the straightness, shortness, &c. of the female urethra, is counterbalanced by the extreme sensibility generally attendant on cases of calculus.

We perform the operation in the following manner:—Introduce a common director into the urethra; set a small scalpel into its groove, with the edge turned upwards; make a wound about three-fourths of an inch directly towards the clitoris; then turn the groove of the director and the cutting edge of the scalpel to the left lateral aspect; press the knife into the bladder, taking care to keep the edge a little downwards; and to start the transverse incision at the upper angle of the first or vertical incision; and, also, that the cutting edge of your knife do not exceed an inch. We will thus avoid all risk of wounding the internal pudic artery, and obtain an opening amply sufficient for the forceps, &c. without in any degree injuring the vagina. Having passed the knife into the bladder, we may now enlarge the wound a little at the neck of the bladder, as we withdraw the instrument. We shall thus obtain quite a sufficient opening, since the outer parts will be found to dilate with the readiest facility.

Having made the incision, we extract the stone agreeably to the rules laid down for the male subject. We may either introduce the tube, as in the male, or pass a pretty deep suture or two to close the wound. We have practised both methods, and found them to succeed alike. There is, however, considerable difficulty in keeping a tube well fastened, and we think, upon the whole, that the suture, without the tube, will be found to be the better method.

We have been led to conclude, that by this method of procedure we shall succeed most readily in obtaining a restoration of parts by the first intention; by this more than half the usual sufferings will be avoided; and, therefore, all things considered, the method by incision being easy, expeditious, safe, and suited to every circumstance of such cases admitting of relief, is preferable to lithontrity.

It would be superfluous to enter into any particular anatomical description in relation to an operation so simple, and where the necessary anatomy must be perfectly familiar to every man qualified to operate. It may not be amiss, however, to state, that we need not injure the clitoris, there being a sufficient space between the urethra and that body to admit of the necessary incision upwards; and, indeed, little more is really necessary in this direction than dividing the urethral tube. In cutting across, we will, in a slight degree, cut into the crus clitoris, on the left side. But the integuments and cellular structures are so dilatable in the parts under consideration, that small incisions answer, and yet the parts have sufficient body and firmness, especially when they become tumid, to stand up firmly; and are easily kept in contact when divided. The incision being on the upper side of the urethra, there is little risk of the urine lodging in the wound. And as any risk which may arise of incontinence from cutting the urethra, must be owing to splitting the urethra on the lower side, and also the vagina, every thing will be obtained that is to be expected from the operation of M. Lisfranc, and our operation is much more simple than his, and will more readily admit of healing by the first intention

We would not, under any circumstances, make a large wound; if the stone be large it may be easily and safely broken. I use quite small scalpels in my operations, and would prefer passing in the left forefinger to direct the knife in enlarging the wound, rather than run the risk of making a wound too large at first. It is only wounds of reasonable extent in lithotomy that we can heal by the first intention, and such wounds will always answer our purposes best; and the advantages of securing such a healing of the wound are incalculable."—*Reese.*]

LOTIO ALUMINIS.—℞. Aluminis purif. ʒ ss. Aquæ distillatæ ℔j. Misce.—Sometimes used as an astringent injection; sometimes as an application to inflamed parts.

LOTIO AMMONIÆ ACETATÆ.—℞. Liq. ammon. acetatæ; Spirit. vin. rectif.; Aquæ distillatæ; sing. ʒ iv. Misce.—Properties discutient.

LOTIO AMMONIÆ MURIATÆ.—℞. Ammon. muriatæ ʒ j. Spirit rosmarini ℔j.—Has the same virtues as the preceding. Justamond recommended it in the early stage of the milk-breast.

LOTIO AMMONIÆ MURIATÆ CUM ACETO.—℞. Ammon. mur. ʒ ss. Aceti, Spirit. vinos. rectif. sing. ℔j. Misce.—This is one of the most efficacious discutient lotions. It is, perhaps, the best application for promoting the absorption of extravasated blood, in cases of ecchymosis, contusions, sprains, &c.

LOTIO AMMONIÆ OPIATA.—℞. Spiritus, ammon. comp. ʒ iiiss. Aquæ distillatæ ʒ iv. Tinct. opii ʒ ss. Misce.—Applied by Kirkland to some suspicious swellings in the breast, soda and bark being also given internally.

LOTIO BORACIS.—℞. Boracis ʒ j. Aq. simplicis ʒ iiis. Spir. vinos. ʒ ss. Misce.—This lotion is recommended by Sir Astley Cooper as one of the best applications to sore nipples.

LOTIO ACIDI PYROLIGNEI.—℞. Acid. pyrolign. ʒ ij. Aq. distillat. ʒ vj. Misce.—This is injected into the meatus auditorius by Mr. Buchanan, for the purpose of improving the secretion within the passage, and stopping morbid discharge from it.—(See *his Illustrations of Acoustic Surgery, 8vo. Lond.* 1825.) In particular cases, attended with much irritability, he uses the following formula:—℞. Plumbi acet. gr. x. Acid. pyrolign. gutt. xx. Aq. distillat. ʒ vj. Misce.

LOTIO CALCIS COMPOSITA.—℞. Liq. calcis ℔j. Hydrargyri submuriatis ʒ j. Misce.—Ring-worms, tetters, and some other cutaneous affections, are benefitted by this application.

LOTIO GALLÆ.—℞. Gallarum contusarum ʒ ij. Aquæ ferventis ℔j. To be macerated one hour, and strained.—This astringent lotion is sometimes used with the view of removing the relaxed state of the parts, in cases of prolapsus ani, prolapsus uteri, &c.

LOTIO HYDRARGYRI AMYGDALINA.—℞. Amygdalarum amararum ℥ ij. Aquæ distill. ℔ij. Hydrarg. oxymuriatis ℈j. Rub down the almonds with the water, which is to be gradually poured on them; strain the liquor, and then add the oxymuriate of mercury.—This will cure several cutaneous affections.

LOTIO HYDRARGYRI OXYMURIATIS.—℞. Hydrargyri oxymuriatis gr. ijss. Arabici gummi ʒ ss. Aquæ distillatæ ℔j. Misce.

LOTIO HYDRARGYRI OXYMURIATIS COMPOSITA.—℞. Hydrarg. oxymur. gr. x. Aq. distillat. bullientis ʒ ss. Tinct. canthar. ʒ ss. Misce.—Applied by Dr. H. Smith to scrofulous swellings.

LOTIO HELLEBORI ALBI.—℞. Decocti hellebori albi ℔j. Potassæ sulphureti ʒ ss. Ol. Lavend. gutt. iv. Misce.—Occasionally applied to tinea capitis, and some other cutaneous diseases.

LOTIO PLUMBI ACETATIS.—℞. Liq. plumbi acet. ʒ ij. Aq. distill. ℔j. Spirit. vinos. tenuioris ʒ ij. The first and last ingredients are to be mixed before the water is added.—The common white wash; an application universally known.

LOTIO POTASSÆ SULPHURETI.—℞. Potassæ sulph. ʒ ij. Aquæ. distill. ℔j. Ol. Lavend. gutt. iv. Misce.—Used in cases of porrigo, psoriasis, lepra, &c.

LOTIO OPII.—℞. Opii purif. ʒ jss. Aquæ distillatæ ℔j. Misce.—A good application to irritable painful ulcers. It is best to dilute it, especially at first.

LOTIO PICIS.—℞. Picis liquidæ ʒ iv. Calcis ʒ vj. Aquæ ferventis ℔iij. To be boiled till half the water is evaporated. The rest is then to be poured off for use.—This application is sometimes employed in tinea capitis; and for the removal of an extensive redness frequently surrounding old ulcers of the legs, in persons whose constitutions are impaired by copious porter drinking, gluttony, and other forms of intemperance.

LOTIO ZINCI SULPHATIS.—℞. Zinci sulphatis ʒ ij. Aq. ferventis ℔j. Misce.—Sometimes used in lieu of the lotio plumbi acet. It forms a good astringent application for a variety of cases. When diluted with one additional pint of water, it is the common injection for gonorrhœa.

LUES VENEREA.—(See *Venereal Disease.*)

LUMBAR ABSCESS.—*Psoas Abscess.*—By these terms are understood chronic collections of matter, which form in the cellular substance of the loins, behind the peritoneum, and descend in the course of the psoas muscle. According to professor Gibson, this disease, which is remarkably common in Europe, is rarely met with in the United States. In the course of thirteen years, during which he has been connected with extensive hospitals, he has seen only four cases; and Dr. Physick had never attended an instance of psoas abscess in America, unconnected with disease of the spine.—(See *Gibson's Institutes, &c. of Surgery, vol.* 1, *p.* 214, *8vo. Philadelphia*, 1824.) Patients in the incipient stage of the disease, cannot walk so well as usual: they feel a degree of uneasiness about the lumbar region; but in general there is no acute pain, even though the abscess may have acquired such a size as to form a large tumour, protruding externally. In short, the psoas abscess is the best instance which can possibly be adduced, in order to illustrate the nature of those collections of matter, which are called chronic, and which form in an insidious manner, without serious pain or any other attendant of acute inflammation.

The abscess sometimes forms a swelling above Poupart's ligament; sometimes below it; and frequently the matter glides under the fascia of the thigh. Occasionally it makes its way through the sacro-ischiatic foramen, and assumes rather the appearance of a fistula in ano. When the matter gravitates into the thigh, beneath the fascia, Mr. Hunter would have termed it a disease *in*, not *of*, the part. The uneasiness in the loins, and the impulse communicated to the tumour by coughing, evince that the disease arises in the lumbar region; but it must be confessed, that we can hardly ever be sure of the existence of the disorder, until the tumour, by presenting itself externally, leads us to such information. The lumbar abscess is sometimes connected with diseased vertebræ, which may either be a cause, or an effect, of the collection of matter. The disease, however, is frequently unattended with this complication.

The disease of the spine, we may infer, is not of the same nature as that treated of by Pott, as there is usually no paralysis. When the bodies of patients with lumbar abscesses are opened, it is found, that the matter is completely enclosed in a cyst, which, in many cases, is of course very extensive. If the contents of such abscesses were not circumscribed by a membranous boundary in this manner, we should find that they would spread among the cells of the cellular substance just like the water in anasarca. The cysts are both secreting and absorbing surfaces, as is proved by the great quantity of matter which soon collects again after the abscess has been emptied, and by the occasional disappearance of large palpable collections of matter of this kind, either spontaneously, or in consequence of means which are known to operate by exciting the action of the absorbents. In short, the cyst becomes the suppurating surface, and suppuration is now well ascertained to be a process similar to glandular secretion. While the abscess remains unopened, its contents are always undergoing a change; fresh matter is continually forming, and a portion of what was previously in the cyst is undergoing the necessary removal by the absorbents. This is not peculiar to lumbar abscesses; it is common to all, both chronic and acute, buboes and suppurations in general. It is true, that in acute abscesses, there often has not been time for the formation of so distinct a membrane as the cyst of a large chronic abscess; but their matter is equally

circumscribed by the cavities of the cellular substance being filled with a dense coagulating lymph; and though it generally soon makes its way to the surface, it also is sometimes absorbed.

The best modern surgeons make it a common maxim to open few acute abscesses; for the matter naturally tends with great celerity to the surface of the body, where ulceration allows it to escape spontaneously; after which, the case generally goes on better than if it had been opened by art. But in chronic abscesses, the matter has not that strong tendency to make its way outward; its quantity is continually increasing; the cyst is, of course, incessantly growing larger and larger; in short, the matter, from one ounce, often gradually increases to the quantity of a gallon. When the disease is at length opened, or bursts by ulceration, the surface of the cyst inflames; and its great extent in this circumstance, is enough to account for the terrible constitutional disorder, and fatal consequences, which too frequently soon follow the evacuation of the contents of such an abscess. Hence, in cases of chronic suppurations of every kind, and not merely in lumbar abscesses, it is the surgeon's duty to observe the opposite rule to that applicable to acute cases; and he is called upon to open the collection of matter, as soon as he is aware of its existence, and its situation will allow it to be done.

This view of the principle on which the treatment of a lumbar abscess should be conducted, is not, however, adopted by all surgeons. Kirkland believed, that the patient had the best chance of recovery, when the abscess was allowed to burst spontaneously, and the matter to be gradually discharged through a small opening (*Kirkland's Medical Surgery, vol.* 2, *p.* 199); and Mr. Pearson, in comparing the results of his own experience, declares them to be in favour of the same practice. The generality of modern surgeons in this country, differ on this point from Kirkland and Pearson; yet, while they advocate the utility of an early puncture, they admit the danger of suddenly discharging the contents of the abscess through a large one, which is afterward left unclosed.

Certainly, it would be highly advantageous to have some means of ascertaining whether the vertebræ are diseased; for, as in this instance the morbid bones would keep up suppuration until their affection had ceased, and there would be no reasonable hope of curing the abscess sooner, it might be better to avoid puncturing it under such circumstances. The propriety of this conduct seems the more obvious, as issues, which are the means most likely to stop and remove the disease of the spine, are also such as afford the best chance of bringing about the absorption of the abscess itself. However, if the collection cannot be prevented from discharging itself, and ulceration is at hand, it is best to meet the danger, make an opening with the lancet in a place at some distance from where the pointing threatens, and afterward heal it in the way which will be presently detailed.

Though we have praised the prudence of opening all chronic abscesses while small, the deep situation of the lumbar one, and the degree of doubt always involving its early state, unfortunately prevent us from taking this beneficial step in the present case. But still the principle is equally praiseworthy, and should urge us to open the tumour as soon as the fluctuation of the matter is distinct, and the nature of the case is evident. For this purpose Mr. Abernethy employs an abscess lancet, which will make an opening large enough for the discharge of those flaky substances so frequently found blended with the matter of lumbar abscesses, and by some conceived to be an emblem of the disease being scrofulous. Such flakes seem to consist of a part of the coagulating matter of the blood, and are very commonly secreted by the peculiar cysts of scrofulous abscesses. The puncture must also be of a certain size, in order to allow the clots of blood, occasionally mixed with the matter, to escape. Mr. Abernethy considers the opening of a lumbar abscess a very delicate operation. Former surgeons used to make large openings in these cases, let out the contents, and leave the wound open; the usual consequences of which were, great irritation and inflammation of the cyst, immense disturbance of the constitution, putrefaction of the contents of the abscess in consequence of the entrance of air into its cavity, and, too often, death. While such practice prevailed, very few afflicted with lumbar abscesses were fortunate enough to escape. The same alarming effects resulted from allowing the abscess to attain its utmost magnitude, and then burst by ulceration. If then a more happy train of events depend upon the manner in which lumbar abscesses are punctured, the operation is certainly a matter of great delicacy.

Until the collection is opened, or bursts, the patient's health is usually little or not at all impaired; indeed, we see in the faces of many persons with such abscesses what is usually understood by the picture of health. Hence, how likely our professional conduct is to be arraigned, when great changes for the worse, and even death, occur very soon after we have let out the matter, seemingly, and truly, in consequence of the operation. Every plan, therefore, which is most likely to prevent these alarming effects, is entitled to infinite praise; and such, I conceive, is the practice recommended by Mr. Abernethy.

This gentleman's method is to let out the matter, and heal the wound immediately afterward by the first intention. He justly condemns all introductions of probes, and other instruments, which only irritate the edges of the puncture, and render them unlikely to grow together again. The wound is to be carefully closed with sticking plaster, and it will almost always heal.

These proceedings do not put a stop to the secretion of matter within the cavity of the abscess. Of course a fresh accumulation takes place; but it is obvious, that the matter, as fast as it is produced, will gravitate to the lowest part of the cyst, and consequently the upper part will remain for some time undistended, and have an opportunity of contracting.

When a certain quantity of matter has again accumulated, and presents itself in the groin, or elsewhere, which may be in about a fortnight after the first puncture, the abscess is to be punctured again in the same manner as before, and the wound healed in the same way. The quantity of matter will now be found much less, than what was at first discharged. Thus the abscess is to be repeatedly punctured at intervals, and the wounds as regularly healed by the first intention, by which method irritation and inflammation of the cyst will not be induced, the cavity of the matter will never be allowed to become distended, and it will be rendered smaller and smaller, till the cure is complete.

In a few instances, the surgeon may, perhaps, be unable to persevere in healing the repeated punctures which it may be necessary to make; but after succeeding once or twice, the cyst will probably have had sufficient opportunity to contract so much, that its surface will not now be of alarming extent. It is also a fact, that the cyst loses its irritability, becomes more indolent and less apt to inflame, after the contents have been once or twice evacuated in the above way. Its disposition to absorb becomes also stronger.

The knowledge of the fact, that the cysts of all abscesses are absorbing surfaces, should lead us never to neglect other means, which Mr. Abernethy suggests, as likely to promote the dispersion of the abscess, by quickening the action of the absorbents. Blisters kept open with savine cerate, issues, electricity, occasional vomits of the sulphate of zinc, are the means most conducive to this object. When the vertebræ are diseased, issues are doubly indicated.

In the latter complication the case is always dangerous. If an opening be made in the abscess, the cyst is at first more likely to be irritated than when the bones are not diseased, and the affection of the spine is rendered much less likely to undergo any improvement, in consequence of the mere formation of an outward communication. The same bad effect attends necrosis; in which case, the absorption of the dead bone is always retarded by the presence of unhealed fistulæ and sores, which lead down to the disease.

Mr. Crowther succeeded in dispersing some large lumbar abscesses without opening them. Large blisters applied to the integuments covering the swelling, and kept open with the savine cerate, effected the cure. When this gentleman punctured such collections of matter, he used a small trocar, which he introduced at the same place as often as necessary. He observes, that the aperture so made does not ulcerate, and allows no matter to escape after being dressed. I cannot, however, discover any reason for his preferring the trocar to the abscess lancet, except that the cannula

enables the surgeon to push back with a probe any flakes of lymph, &c. which may obstruct its inner orifice. But this is scarcely a reason, when Mr. Abernethy informs us that the opening made with an abscess lancet is large enough to allow such flakes to be discharged; and when they stop up the aperture a probe might also be employed to push them back. A wound made with a cutting instrument will, *cæteris paribus*, always unite more certainly by the first intention than one made with such an instrument as a trocar. Mr. Crowther may always have succeeded in healing the aperture; but I do not believe that other practitioners would experience equal success. Were the tumour not very prominent, from the quantity of matter being small, suddenly plunging in a trocar might even endanger parts which should on no account be injured.

Some surgeons open lumbar abscesses with a seton. The matter being made to form as prominent a swelling as possible, by pressing the abdomen, and putting the patient in a position which will make the contents of the abscess gravitate towards the part where the seton is to be introduced, a transverse cut is first to be made in the integuments down to the fascia. A flat trocar is next to be introduced within the incision, which should only be just large enough to allow the instrument to pass freely under the skin for at least three quarters of an inch; when the hand is to be raised, and the trocar pushed obliquely and gently upwards till the cannula is within the lower part of the sac. The trocar must now be withdrawn, and the matter allowed to flow out gently, stopping it every now and then for some minutes. The assistant must now withdraw his hand to take away the pressure, and place the thumb of his left hand upon the opening of the cannula, holding it between his fore and middle fingers. It must then be pushed upwards, nearly to the top of the tumour, where its end may be distinctly felt with the fore-finger of the right hand. As soon as it can be plainly felt, it must be held steadily in the same position, and the trocar is to be introduced into it again and pushed through the skin at the place where it is felt, and the cannula along with it. The trocar being next withdrawn, a probe with a skein of fine soft silk dipped in oil must be passed through the cannula, which being now taken away leaves the seton in its place. A pledget of mild ointment is then to be applied over the two openings, the more completely to exclude the air. A fresh piece of the silk is to be drawn into the abscess, and that which was in before cut off, as often as necessary.—(See *Latta's System of Surgery, vol.* 3, *p.* 307.)

Deckers, who wrote in 1696, discharged a large abscess in a gradual manner with a trocar, the cannula of which was not withdrawn, but stopped up with a cork and the matter let out at intervals. B. Bell also advises the cannula not to be taken out.

I cannot quit this subject without mentioning a remarkable case of lumbar abscess, which I once saw in Christ's Hospital, under the care of the late Mr. Ramsden. The tumour extended from the ileum and sacrum below, as high up as the ribs. The diameter of the swelling, from behind forwards, might be about six or eight inches. It was attended with so strong a pulsation corresponding with that of the arteries, that several eminent surgeons in this city considered the case as an aneurism of the aorta. After some weeks, as the tumour increased in size, the throbbing of the whole swelling gradually became fainter and fainter, and at length could not be felt at all. The tumour was nearly on the point of bursting. Mr. Ramsden suspected that it was an abscess, and determined to make a small puncture in it. The experiment verified the accuracy of his opinion; a large quantity of pus was evacuated at intervals; but the boy's health suffering, he went to his friends at Newbury, and I did not afterward hear the event. I have never seen any popliteal aneurism whose pulsations could be more plainly seen and strongly felt, than those of the abscess we have just been describing A singular case is related by Mr. Wilmot of a psoas abscess, the matter of which was at length absorbed, and its cavity filled with air, attended with a considerable increase in the size of the tumour, a conical elongated shape, and elastic feel, instead of a fluctuation, previously quite evident, and the subsidence of all the hectical symptoms. A complete dispersion of the swelling was effected by a bandage and compress wet with a strong decoction of oak bark and alum.—(See *Kirkland's Med. Surgery, vol.* 2. *Trans. of the King's and Queen's College of Physicians in Ireland, vol.* 2, *p.* 26, *&c.* 8*vo. Dublin*, 1818. *F. Schoenmezel, Obs. de Musculis Psoa et Iliaco suppuratis, Frank. M

MAMMA, REMOVAL OF, AND DISEASES OF. The operation of cutting away a diseased breast is done nearly in the same manner as the removal of tumours in general, and is indicated whenever the part is affected with a disease which is incurable by external or internal remedies, but admits of being entirely removed with the knife. When the breast is affected with scirrhus, or ulcerated cancer, the imprudence of tampering with the disease cannot be too severely censured. Were the disorder unattended with a continual tendency to increase, some time might properly be dedicated to the trial of the internal remedies and external applications which have acquired any character for doing good in these unpromising cases. But, unfortunately, by endeavouring to cure the disease by medicine, we only afford time for it to increase in magnitude, and at length attain a condition in which even the knife cannot be employed so as to take away the whole of the diseased parts. When the case is marked by the characteristic features of scirrhus, noticed in the article *Cancer*, the sooner the tumour is cut out the better. There are also some malignant kinds of sarcoma, to which the female breast is subject (as will be explained in the article *Tumour*), which cannot be removed at too early a period after their nature is suspected or known. Indeed, though there is not equal urgency for the operation when the tumour is only an indolent, simple, fatty, hydatid, or sarcomatous disease, yet as all these tumours are continually growing larger, and little success attends the attempt to disperse them, the practitioner should never devote much time to the trial of unavailing medicines and applications, and let the swelling attain a size which would require a formidable operation for its excision. It is also to be remembered, that many simple, fleshy, indolent tumours are accompanied with a certain degree of hazard of changing into very malignant forms of disease.

With respect to what Sir A. Cooper calls the *hydatid*, or *encysted swelling of the breast*, he describes two forms of it; one containing a fluid like serum, in cells, the other being a globular hydatid, such as is found in the liver and other parts. The breast gradually swells, and in the beginning is entirely free from pain or tenderness. It becomes hard; no fluctuation can then be discovered in it; and it continues to grow slowly for months, and even for years. The part is painful only just before the period of the menses. After a time, some points of the swelling feel as if they contained fluid, while the rest continues firm. The skin is quite free from discoloration, except immediately before it begins to ulcerate. The constitution suffers no par-

ticular disturbance except when ulceration commences, and then it is only slight. Sir A. Cooper has never seen an instance of this disease being cured by a natural process; it remains for months and years; the cysts breaking one after another, and the breast wasting, till little of it remains. He has seen more cases of this complaint between the ages of fifteen and twenty-five than at other periods of life; but he has also sometimes met with it in older subjects, and one case in an individual more than sixty. The disease sometimes acquires an extraordinary magnitude. The tumour is extremely moveable upon the pectoral muscle, and very pendulous. It never requires to be removed on account of any malignancy in its character; but the operation is done to relieve the patient from its inconvenience, and to satisfy her mind. Although the whole breast should be involved in the disease, and the swelling discharge largely, put on a formidable appearance, and even become of enormous size, the glands in the axilla remain entirely free from disease; or if one be slightly enlarged, it is merely from simple irritation, and it disappears when the complaint in the breast is removed. There is no danger of the disease extending by absorption, or of its producing any mischief beyond the breast; nor has Sir Astley Cooper ever known it attack both mammæ at the same time. But, though such is the unmalignant nature of the disease, all the tumour and induration must be removed if an operation be necessary; for, otherwise, any hydatid cyst left behind will continue to grow, and the hydatid swelling of the breast to enlarge.—(*Illustrations of Diseases of the Breast*, p. 22—26.) When the cyst has been single, Sir A. Cooper has sometimes let out the fluid with a lancet, and the adhesive and suppurative inflammation, thus excited, has terminated in a cure.—(See *Lancet*, *vol.* 2, *p.* 368—370.)

The disease in its first stage resembles simple chronic inflammation; but it may be distinguished from it by the absence of tenderness on pressure; and the perfect health in which the patient remains marks it as quite a local disease. In its second stage, when it fluctuates, its nature is indicated by the several distinct seats of the fluctuation; but, as Sir Astley Cooper adds, the best criterion is afforded by the puncture of the cyst, whereby a clear serum is let out, and not a purulent fluid.—(*Illustrations of Diseases of the Breast*, p. 24.) It is distinguished from scirrhus by its freedom from the occasional acute darting pains, and great hardness of the latter affection, and by the health being undisturbed. Sir Astley Cooper, however, has seen a case in which a scirrhus was complicated with hydatids; and so has the author of this work. In such examples, of course, the disease is attended with the usual lancinating pains, and all the other evils of a carcinomatous tumour.

Besides this and other hydatid swellings of the breast, and scirrhus and fungus hæmatodes (see *Cancer* and *Fungus*), Sir A. Cooper notices the case named *Simple Chronic Tumour of the Breast*. It is generally met with in persons from seventeen to thirty years of age, and of healthy appearance, is exceedingly moveable, more diffused in the surrounding substance than scirrhus, and has a lobulated feel, like that of a fatty swelling. He affirms that it is a disease which never becomes cancerous, or rather never unless it continue till the period of life when the uterine secretion terminates (see *Illustrations of Diseases of the Breast*, *p.* 63), though it may attain a large size, and be attended with pain at the period of menstruation. Its ordinary size is from that of a filbert to that of a billiard-ball. It does not admit of being dispersed by medicine, but can easily be taken away by incision. It seems to grow on the surface of the breast, rather than from its interior; and it therefore appears to be very superficial, unless when it arises from the posterior surface of the mammary gland, in which case it is deeply seated, and its peculiar features less clear.

This chronic mammary tumour may continue nearly stationary for many years, and then gradually diminish. Sir Astley Cooper has known a gland enlarge in the axilla, and I am now attending a patient with a similar change (August, 1829), but it is considered a rare occurrence, and merely the result of irritation.—(See *Illustrations of Diseases of the Breast*, *p.* 53.) The same surgeon regards the disease as sympathetic with the state of the uterus; and although he does not think the case much within the power of medicine, he prescribes, if the digestive functions be disordered, the compound calomel pill to be taken at night, and the infusion of columba with rhubarb and the carbonate of soda, twice a day. When the uterine secretion is defective, he exhibits small doses of the blue pill and colocynth with steel medicines. As local applications, he prefers the emplastr. ammon. cum hydrargyro, and the iodine ointment. The disease, however, rarely yields till the uterine excitement ceases, or the part is required to furnish its own natural secretion. Hence, Sir Astley Cooper deems the complaint no objection to matrimony, as it is likely to be benefited by it.—(*Vol. cit.*, *p.* 57.)

The same excellent surgeon has also described another form of disease, which he calls the *Irritable Tumour of the Breast*. It occurs in persons aged from 15 to 25, a period of life scarcely liable to cancer; the part is so extremely sensible, that the patient starts on its being touched, and although it is commonly painful, yet just before the time of the menses the agony from it is almost incredible, the pain extending from the breast to the arm down to the fingers' ends, and even sometimes affecting the sight. The removal of the breast, on account of this affection, is completely unnecessary.

The treatment consists in lessening the irritability of the system, diminishing the pain, and restoring menstruation. As local applications, Sir A. Cooper recommends a plaster composed of equal parts of soap plaster and extract of belladonna, or a poultice with solution of belladonna and bread. Oil-skin or hare-skin worn upon the breast, he also deems useful. When the pain is excessive, he sanctions the employment of leeches; but thinks them productive of weakness and of an increase of irritability, when too often used. As constitutional remedies, he gives the submuriate of mercury with opium and conium; or, for lessening the irritability of the part, a pill composed of two grs. of the extract of conium, two grs. of the extract of poppy, and one-half of a gr. of the extract of stramonium, two or three times a day. For restoring the uterine secretion, he prescribes the carbonate of iron ferrum ammoniatum, or the mixtura ferri comp. Each of these may be combined with aloes. He also recommends a hip-bath of sea or salt water, heated to 100 or 105°.—(See *Illustrations of Diseases of the Breast*, *p.* 79.)

The breast is also liable to scrofulous swellings, to a morbid growth called by Sir Astley Cooper the large and pendulous breast, to adipose tumours, and to the cartilaginous, as well as some other diseases described in the articles *Cancer*, *Fungus Hæmatodes*, and *Tumour*.

It cannot be denied that there are many swellings and indurations of the breast, which it would be highly injudicious and unnecessary to extirpate, because they generally admit of being discussed. Such are many tumours which are called *scrofulous*, from their affecting patients of this peculiar constitution, cases in which the trial of iodine internally and externally may very properly be made.—(See *Iodine*.) Such are nearly all those indurations which remain after a sudden and general inflammatory enlargement of the mamma; such are most other tumours, which acquire their full size in a few days, attended with pain, redness, &c.; and of this kind, also, are the hardnesses in the breast, occasioned by the mammary abscess.

In the removal of all malignant or cancerous tumours, their nature makes it necessary to observe one important caution in the operation, viz. not to rest satisfied with cutting away the tumours just at their circumference; but to take away also a considerable portion of the substance in which they lie, and with which they are surrounded. In cutting out a cancerous breast, if the operator were to be content with merely dissecting out the disease just where his eyes and fingers might equally lead him to suppose its boundary to be situated, there would still be left behind white diseased bands, which radiate from the tumour into the surrounding fat, and which would inevitably occasion a relapse. In a vast proportion of the cases also in which cancer of the breast unfortunately recurs after the operation, it is found that the skin is the part in which the disease makes its reappearance. Hence the great prudence of taking away a good deal of it in every case suspected to be a truly scirrhous or cancerous disease. This may also be done so as not to

prevent the important objects of uniting the wound by the first intention, and covering the whole of its surface with sound integuments. So frequently does cancer recur in the nipple, whenever it does recur any where, that many of the best modern operators always make a point of removing this part in every instance in which it is judged expedient to take away any portion of the skin at all. The surgeon indeed would be inexcusable were he to neglect to take away such portion of the integuments covering scirrhous tumours as is evidently affected, appearing to be discoloured, puckered, and closely attached to the diseased lump beneath. Nor should any gland in the axilla at all diseased, nor any fibres of the pectoral muscle in the same state, be ever left behind. There is no doubt that nothing has stamped operations for cancers with disrepute so much as the neglect to make a free removal of the skin and parts surrounding every side of the tumour. Hence the disease has frequently appeared to recur, when in fact it has never been thoroughly extirpated; the disease, though perhaps a local affection, has been deemed a constitutional one; and the operation frequently rejected as ineffectual and useless.

But strongly as I have urged the prudence, the necessity, of making a free removal of the skin covering, and of the parts surrounding, every cancerous or malignant tumour, the same plan may certainly be regarded as unnecessary, and therefore unscientific, in most operations for the removal of simple, fatty, fleshy or encysted tumours, to which the breast and almost every other part is liable. However, even in the latter cases, when the swelling is very large, it is better to take away a portion of skin; for otherwise, after the excision of the tumour, there would be a redundance of integuments, the cavity of which would only serve for the lodgement of matter. The loose superfluous skin also would lie in folds, and not apply itself evenly to the parts beneath, so as to unite favourably by the first intention; nor could the line of the cicatrix itself be arranged with such nice evenness as it might have been, if a part of the redundant skin had been taken away at the time of operating.

The best method of removing a diseased breast is as follows: the patient is usually placed in a sitting posture, well supported by pillows and assistants; but the operator will find it equally convenient, if not more so, to remove the tumour while his patient is in a recumbent position; and this posture is best whenever the operation is likely to be long, or much blood to be lost, which circumstances are very apt to bring on fainting. I remember that Mr. Abernethy, in his lectures, used to recommend the latter plan; which, however, without the sanction of any great name or authority, possesses such obvious advantages as will always entitle it to approbation.

If the patient be in a sitting posture, the arms should be confined back by placing a stick between them and the body, by which means the fibres of the great pectoral muscle will be kept on the stretch, a state most favourable for the dissection of the tumour off its surface. The stick also prevents the patient from moving her arm about, and interrupting the progress of operation.

When the tumour is not large, and only a simple sarcoma, free from malignancy, it will be quite unnecessary to remove any of the skin, and of course this need only be divided by one incision of a length proportionate to the tumour. The cut must be made with a common dissecting knife; and as the division of the parts is chiefly accomplished with the part of the edge towards the point, the instrument will be found to do its office best when the extremity of the edge is made of a convex shape, and this part of the blade is turned a little back in the way in which dissecting knives are now often constructed. The direction of the incision through the skin should be made according to the greatest diameter of the tumour to be removed, by which means it will be most easily dissected out.

The direction of the incision is various with different practitioners; some making it perpendicular, others transverse. In general, the shape of the tumour must determine which is the best. In France it has been said that when the incision follows the second direction it heals more expeditiously, because the skin is more extensible from above downwards than laterally, particularly towards the sternum, and consequently allows the sides of the wound the more readily to be placed in contact; and that the action of the pectoral muscle tends to separate the edges of the wound when it is perpendicular. On the other hand, it is allowed that the wound made in the latter manner is the most favourable for the escape of the discharge, if suppuration should occur.—(See *Œuvres de Desault, par Bichat*, *p.* 312, *t.* 2.)

The cut through the skin should always be somewhat longer than the tumour, and as it is perhaps the most painful part of the operation, and one attended with no danger whatever, it should be executed with the utmost celerity, pain being more or less dreaded according to its duration, as well as its degree. The fear, however, of giving pain has probably led many operators to err, in not making their first incision through the integuments large enough, the consequence of which has often been, that there was not sufficient room for the dissection of the tumour with facility; the patient has been kept nearly an hour in the operating room, instead of five minutes, and the surgeon censured by the spectators as awkward and tedious. It is clear also that besides the larger quantity of blood lost from this error than would otherwise happen, the vessels being commonly not tied till all the cutting is finished, the avoidance of pain, that fear which led to the blunder, is not effected, and the patient suffers much more and for a much longer time, in consequence of the embarrassment and obstacles in the way of the whole operation.

When the disease is of a scirrhous or malignant nature, the skin covering the tumour should, at all events, be in part removed. As I have said before, all that portion which is discoloured, puckered, tuberculated, or otherwise altered, should be taken away. Some must also be removed in order to prevent a redundance in all cases in which the tumour is large. We have said too, that in cases of scirrhus and cancer of the breast, the nipple is considered a dangerous part to be left behind. For the purpose of removing the necessary portion of skin, the surgeon must obviously pursue a different mode from that above described; and instead of one straight incision he is to make two semicircular cuts, one immediately after the other, and which are to meet at their extremities. The size of these wounds must be determined by that of the disease to be removed, and by the quantity of skin which it is deemed prudent to take away; for the part which is included in the two semicircular cuts is that which is not to be separated from the upper surface of the swelling, but taken away with it. The shape of the two cuts together may approach that either of a circle or oval, as the figure of the tumour itself may indicate as most convenient. The direction of the incisions is to be regulated by the same consideration.

In the above ways, the first division of the integuments is to be made in removing tumours of every description covered with skin. The same principles and practice should prevail in all these operations; and whether the swelling be the mamma or any other diseased mass, whether situated on the chest, the back, the head or extremities, the same considerations should always guide the operator's hand.

The incision or incisions in the skin having been made, the next object is to detach every side of the tumour from its connexions, and the separation of its base will then be the last and only thing remaining to be done. When the tumour is a scirrhous or other malignant disease, the operator must not dissect close to the swelling, but make his incisions on each side, at a prudent distance from it, so as to be sure to remove, with the diseased mass, every atom of morbid mischief in its vicinity. But when the tumour is only a mere fatty or other mass, perfectly free from malignancy, the cellular bands and vessels forming its connexions may be divided close to its circumference. It is astonishing with what ease fatty tumours are removed, after the necessary division is made in the skin; they may almost be turned out with the fingers without any cutting at all. When they have been inflamed, however, they are considerably more adherent to the surrounding parts.

Thus we see that the first stage of operation of removing a tumour, is the division of the skin; the second, the separation of the swelling from the surrounding parts on every side; the third and last, the division of the parts to which its under surface or base is attached. The latter object should be accomplished by

cutting regularly from above downwards, till every part is divided.

It is a common thing to see many operators constantly embarrassed and confused, whenever they have to remove a large tumour, on account of their having no particular method in their proceedings. They first cut a few fibres on one side; then on another; and, turning the mass of disease now to this side, now to that, without any fixed design, they both prolong the operation very tediously, and present to the bystanders a complete specimen of surgical awkwardness. On the contrary, when the practitioner divides the cutting part of the operation into the three methodical stages above recommended, in each of which there is a distinct object to be fulfilled, he proceeds with a confidence of knowing what he is about, and soon effects what is to be done with equal expedition and adroitness.

Having taken out the tumour, the operator is immediately to tie such large vessels as may be pouring out blood; indeed, when the removal of the swelling will necessarily occupy more than three or four minutes, it is better to tie all the large arteries as soon as they are divided, and then proceed with their dissection. This was the celebrated Desault's plan, and it is highly deserving of imitation, not only because many subjects cannot afford to lose much blood, but also because the profuse effusion of this fluid keeps the operator from seeing what parts he is dividing. For the same reasons, Mr. Morgan's plan of compressing the subclavian artery from above the clavicle, during the operation, so as to prevent hemorrhage, is entitled to praise, especially when the tumour is large, the patient already debilitated, and the operation likely to be tedious.

The largest arteries being tied, the surgeon should not be immediately solicitous about tying every bleeding point which may be observed. Instead of this let him employ a little while in examining every part of the surface of the wound, in order to ascertain that no portion of the swelling, no hardened lump, nor diseased fibres remain behind. Even if any part of the surface of the pectoral muscle should present a morbid feel or appearance, it must, on every account, be cut away. Also, if any of the axillary glands should be diseased, the operator now ought to proceed to remove them. After the time spent in such measures, many of the small vessels, which bled just after the excision of the swelling, will now have stopped, the necessity for several ligatures will be done away, and, of course, the patient saved a great deal of pain, and more of the wound be likely to heal by the first intention.

Some information may be derived respecting whether any of the tumour is left behind, by examining its surfaces when taken out, and observing whether any part of them is cut off; for, if it is, it may always be found in the corresponding part of the wound.

The axillary glands may invariably be taken out, without the least risk, if the plan pursued by Desault in France, and the late Sir Charles Blicke, and other eminent surgeons in this country, be adopted. The method alluded to is, after dividing the skin covering the gland, and freeing the indurated part from its lateral connexions, to tie its root or base, by which it is connected with the parts on the side towards the cavity of the axilla. Then the indurated gland itself may be safely cut off, just above the ligature. Were the gland cut off in the first instance, the artery which supplies it with blood would be exceedingly difficult to tie, on account of its deep situation; and by reason of its shortness and vicinity to the heart, it would bleed almost like a wound of the thoracic artery itself. In this way, there is also not the least hazard of injuring the lateral vessel. It would be a great improvement in the mode of operating for the removal of these glands, if surgeons were always to make the patient lie down, with the arm placed in such a position as would let the light fall into the axilla. How much the steps of the operation would be facilitated in this way, I need not attempt to explain.

The above directions will enable a surgeon to remove tumours in general. They apply also in a great measure to *encysted tumours*; but a few particular rules how to operate in the latter cases, will be found in the article *Tumours*. One-half of each ligature is always to be cut off before dressing the wound. The edges of the incision are to be brought together with strips of adhesive plaster; and before this can be done with ease, the stick confining the arm back must be removed, and the os brachii brought forwards, so as to relax the pectoral muscle and integuments of the breast. No sutures should ever be employed, as they are useless, painful, and irritating. The wound being closed with sticking plaster and a pledget of simple cerate, a compress of folded linen or flannel may be put over the dressings; these are to be secured with a broad piece of linen, which is to encircle the chest, be fastened with pins or stitches, and kept from slipping down by two tapes, one of which is to go from behind forwards, over each shoulder, and be stitched to the upper part of the bandage, both in front and behind. The arm on the same side as that on which the operation has been done, should be kept perfectly motionless in a sling; for every motion of the limb must evidently disturb the wound, by putting the great pectoral muscle into action, or rendering its fibres sometimes tense, sometimes relaxed. It is scarcely necessary to say, that after so considerable an operation as the removal of a large breast, or any other tumour of magnitude, the patient should be given about thirty drops of the tinctura opii. A smaller dose always creates restlessness, headache, and fever, after operations, instead of having the desired effect.

Here it becomes me to state, that as I could not find in any surgical book with which I am acquainted, what I conceived to be a proper description of the mode of removing a diseased breast, and tumours in general, the foregoing remarks are given chiefly on my own authority. Whether they are just or not, must be decided by the profession.

The removal of a diseased breast rarely proves fatal of itself, unless the parts cut away extend to a considerable depth, and occupy a very large space, or the patient is much reduced before the operation. However, I have known one or two patients in St. Bartholomew's Hospital die, without any very apparent cause, very soon after the operation; and Schmucker has recorded an instance in which the operation was followed by tetanus.—(*Wahrnehmungen, b.* 2, *p.* 80.) I believe, that within the last five years, one case has terminated fatally from a similar cause, in St. Bartholomew's.

With respect to the average success following the removal of cancerous diseases, this is a topic which has been noticed in the article *Cancer*. The statement made by Baron Boyer, is exceedingly unfavourable; for, in one hundred cases, in which he has removed the diseased parts, only four or five of the patients continued radically cured.—(*Traité des Mal. Chir. t.* 7, *p.* 237, 8*vo. Paris*, 1821.)

MAMMARY ABSCESS. *Milk abscess.* With regard to inflammations of the mamma, as my friend Mr. James has observed, there is "either simple phlegmon, or mammary abscess, which, as it depends upon a peculiarity of state and function, ought to stand alone. Mr. Hey also describes a deep-seated abscess, to which this gland is liable, or rather a chronic character, and is the same, perhaps, as that which Dr. Kirkland has described as the encysted. Dr. K. describes also two others, under the titles of chronic and encysted." Certain cases, most frequently occurring in unmarried females, and having very little tendency to suppuration, Mr. James suspects are the result of inflammation of the glandular part of the breast from disorder in the digestive organs, uterine system, or both.—(*On Inflammation, p.* 171.) The *lacteal* or *lactiferous tumour*, as it is called by Sir Astley Cooper though attended with fluctuation, is very different from an abscess, and should never be confounded with it. The cause of this swelling is a chronic inflammation and obstruction of one of the lactiferous tubes near the nipple. When the distention is excessive, ulceration sometimes takes place, and the milk is discharged through a small aperture; and when the infant sucks, most of this nutritious fluid is lost to it. The following treatment of the lactiferous swelling is advised by Sir Astley Cooper. If the child can be weaned, a simple puncture will suffice; but if suckling be continued, a larger opening must be made, and the milk suffered to escape at the artificial aperture while the infant is sucking. Relief may thus be obtained until the child is weaned, and the secretion of milk is stopped by purgatives.—(See *Illustrations of Diseases of the Breast, p.* 16.)

Women who suckle are particularly subject to inflammation and suppuration of the breast. The part

enlarges, becomes tense, heavy, and painful. The integuments of the breast sometimes assume a uniform redness; sometimes they are only red in particular places. The inflammation may affect the mammary gland itself, or be confined to the skin and surrounding cellular substance. In the latter case, the inflamed part is equally tense; but when the glandular structure of the breast is also affected, the enlargement is irregular, and seems to consist of one or more large tumours, situated in the substance of the part. The pain often extends to the axillary glands. The secretion of the milk is not always suppressed when the inflammation is confined to the integuments, and suppuration is said to come on more quickly than in the affections of the mammary gland itself. When the symptoms of inflammation continue to increase for four or five days, suppuration may be expected; unless the progress of the inflammation be slow, and its degree moderate, in which circumstances resolution may often be obtained, even as late as a fortnight after the first attack. Acute inflammation of the breast is generally attended with more or less sympathetic inflammatory fever.—(See *Fevers*.) According to the valuable description lately given of the case by Sir Astley Cooper, it is adhesive in the first stage, suppurative in the second, and ulcerative in the third. Swelling is followed by a blush of inflammation upon the surface of the breast, and throbbing very acute pain. "A particular prominence and smoothness are observed at one part of the tumour, with a sense of fluctuation from the presence of matter. The constitution is also highly irritated, which is evinced by the occurrence of shivering, succeeded by heat and profuse perspiration. Over the most prominent part of the swelling, the cuticle separates, ulceration follows in the cutis, and the matter becomes discharged through the aperture thus produced."—(*Illustrations of Diseases of the Breast*, *p*. 7.)

Women are most liable to mammary abscesses within the first three months after parturition; but they are also much exposed to the disorder as long as they continue to suckle.

The most common causes of mammary abscess, as enumerated by writers in general, are, repressing the secretion of milk at an early period, mental disturbance, fright, &c.; exposure to cold, moving the arms too much while the breasts are large and distended, bruises, and other external injuries. The causes are not always obvious. In Sir Astley Cooper's opinion, the principal cause of acute inflammation and suppuration of the breast, is "the rush of blood, which takes place each time the child is applied to the bosom, and which by nurses is called the *draught*, and is the preparatory step to the secretion of milk." He also adverts to the frequent exposure of the bosom in suckling, and the active exertions of the child in sucking, as promoting the origin of the complaint. The nurse, he says, often produces these abscesses immediately after the lying-in, by not putting the child soon enough to the breast, and by giving the mother strong drink.—(See *Illustrations of Diseases of the Breast*, *p*. 8.)

The matter is sometimes contained in one cyst or cavity; sometimes in several; but the abscess generally breaks near the nipple.

As all inflammations of the mamma are attended with considerable induration, these cases should be carefully distinguished from other swellings of a more incurable kind. It is said that scrofulous tumours of the mamma, which have existed a long while, often disappear after the occurrence of a milk abscess. Women who have never been pregnant are sometimes affected with suppuration in the breast, supposed by Mr. James to be connected with uterine or gastric disorder. Even men are liable to abscesses of the breast.

In the early period of the affection, resolution should be attempted. The following are the principal means for this purpose:—venesection, leeches; purges of castor oil, or sulphate of magnesia; low diet, keeping the inflamed breast from hanging down; resting the arm in a sling; fomentations; having the milk tenderly sucked out at proper intervals; saturnine applications, containing spirit of wine; or lotions of the muriate of ammonia. "If the patient suffer from the cold produced by the evaporation of the spirit, a simple tepid poultice may be substituted for it, occasionally applying leeches, and still recollecting that the chief dependence is upon purging."—(See *A. Cooper's Illustrations of Diseases of the Breast*, *p*. 9.)

When matter cannot be prevented from forming, an emollient poultice is a good application; or the surgeon may apply "fomentations of poppy decoction, and poultices made with the same decoction, mixed with bread," which last should be renewed three or four times a day. In order to lessen the patient's sufferings, Sir Astley Cooper prescribes opium combined with the liquor ammoniæ acetatis, or simple saline draughts with small doses of sulphate of magnesia. In general, the abscess should be allowed to break of itself, unless it should be rather of a chronic nature, in which case it may be opened in a depending part with a lancet. Much difference of opinion prevails respecting the practice of opening abscesses of the breast. I consider Sir Astley Cooper's directions extremely useful. "If (says he) the abscess be quick in its progress, if it be placed on the anterior surface of the breast, and if the sufferings which it occasions are not excessively severe, it is best to leave it to its natural course. But if, on the contrary, the abscess in its commencement be very deeply placed, if its progress be tedious, if the local sufferings be excessively severe, if there be a high degree of irritative fever, and the patient suffer from profuse perspiration and want of rest, much time is saved, and pain avoided, by discharging the matter with a lancet."—(See *Illustrations of Diseases of the Breast*, *p*. 10.) The same experienced surgeon disapproves, however, of introducing the lancet through a thick covering of the abscess, as the opening will not procure a free discharge of the matter, but will heal by adhesion, after which the accumulation of matter will continue. The opening, he says, should be made where the matter is most superficial, and the fluctuation is distinct, and its size should be in proportion to its depth. Sinuses sometimes form, and will not heal till freely opened with a director and curved bistoury. When the cavity of the abscess begins to be filled up with granulations, the poultice may be left off, and superficial dressings applied.

For dispersing the considerable induration, which sometimes continues a long while after the abscess is cured, the most effectual plans are friction with camphorated mercurial ointment, the iodine ointment, or the soap liniment with 3 j of the tinct. iodine to each ounce of it, and the occasional exhibition of purgative medicines, with tonics, or the compound calomel pill, according to the state of the constitution.

If the abscess be small, Sir Astley Cooper allows the child to suck the affected breast as well as the other; but if much of the mamma be involved in the disease he lets the infant suck the other breast, and directs the mother to draw the other herself by means of the glass tube constructed for the purpose. When the child is prevented from sucking by excoriations or ulcers of the nipple, the milk accumulates in large quantity, and inflammation is excited. Here Sir Astley also recommends the breast to be drawn; but he thinks, that the sooner the child can be restored to it the better. He deems a solution of a drachm of borax in three ounces and a half of water, and half an ounce of spirit of wine, the best application for a sore nipple. Many practitioners use diluted brandy, lotions of zinc or alum, or that of calomel and lime-water. Sir Astley finds that ointments do not generally agree with the part; but if used, he prefers that of bismuth, or zinc, or simple cerate.

Sometimes, when the swelling is opened, a considerable quantity of milk is discharged: in this case, Sir A. Cooper recommends a sponge tent to be introduced into the puncture, by which means the adhesive inflammation and obliteration of the cavity will be produced.—(See *Lancet*, *vol*. 2, *p*. 406.)

Mr. Hey describes a very deep-seated abscess of the breast not of frequent occurrence, and not confined to pregnant nor suckling women. Its situation renders all superficial applications ineffectual. The inflammatory stage is tedious; and when the matter has made its way outwards, the discharge continues, and there is no tendency to healing. Sometimes the matter lodges behind the mamma, as well as in the substance of the gland, and breaks out in different places, the intermediate parts of the breast feeling as if affected with a scirrhous hardness. Numerous sinuses run in different directions, and, when opened, a soft purple fungus appears within them. The disease goes on in

this state, for a long while, keeping up hectic symptoms.

Mr. Hey's practice was to trace the course of all the numerous sinuses, and lay them open, and he asserts, that unless this be done with respect to every one of them, the cure cannot be accomplished. If he found any two sinuses running in such directions, that when fully opened they left a small part of the mamma in a pendulous state, he removed such part entirely. As the sinuses are filled with fungus, their continuations present no visible cavity, and can only be detected by the greater softness of parts of the wound, where, on breaking down the fungus, the orifice of the collateral sinus may be found. Mr. Hey has found, that even in the most unfavourable subjects, the wounds heal quickly, and the natural shape of the breast is preserved.

The foregoing treatment, it must be confessed, is severe; and if milder measures will answer, they should be preferred. Instead of laying all the sinuses open, Sir Astley Cooper injects them with a lotion composed of rose-water and two or three drops of strong sulphuric acid to each ounce of it, folded linen, wet with the same application, being also laid over the breast. When a deep-seated abscess forms between the ribs and the posterior surface of the breast and bursts, so as to be attended with a sinus, and a tedious exfoliation of the ribs, Sir Astley Cooper considers the injection of diluted acids the best practice; for, unless the dead bone be loose, no advantage can result from the division of the sinus.—(*Illustrations of Diseases of the Breast*, *p.* 11.)

The breast is also liable to chronic abscesses, the formation of which is sometimes so slow and free from pain, that the cases are mistaken for fleshy solid tumours. The treatment recommended by Sir A. Cooper consists in letting out the matter, and giving tonic medicines; but if the disease be in an early stage, and matter should not yet have been formed, the pil. hydrarg. submur. comp. may be prescribed with bark and soda, or the compound infusion of gentian with soda and rhubarb. To the tumour itself the emplastrum ammoniaci cum hydrargyro, or a lotion containing muriate of ammonia and spirit of wine, may be applied.—(See *Sir A. Cooper's Illustrations of Diseases of the Breast*, *p.* 14, *&c.*)

MELICERIS. (From μελι, honey, and κηρος, wax.) A tumour of the encysted kind, filled with a substance resembling wax or honey in consistence.—(See *Tumours*, *Encysted.*)

MENINGOPHYLAX. (From μηνιγξ, a membrane, and φυλασσω, to guard.) An instrument used by the ancients for guarding the dura mater and brain from injury in their mode of trepanning. It seems to have been something like the lenticular, only its blade was completely round without an edge. It ended in a lentiform cup, like the latter.—(*Encyclopedie Méthodique*, *Partie Chir.*) Pott gives an engraving of a meningophylax which resembles a common elevator.—(See *Vol.* 1 *of his Works.*)

MERCURY. (*Quicksilver*, *Mercurius*, *Hydrargyrus.*) The medicinal virtues of this mineral were almost totally unknown to the ancients, who considered it as a poison. It was first employed for purposes of medicine by the Arabians, who made use of it in the form of ointments for the cure of certain diseases of the skin and the killing of vermin. In modern times, mercury is one of the most important articles of the materia medica; and perhaps, though recent investigations will not strictly allow it to be regarded as a specific for the venereal disease, which may be cured by other means, or sometimes even spontaneously, while mercury, so far from being always a certain cure, is sometimes highly detrimental, yet notwithstanding these facts, mercury still retains the character of being generally the most expeditious means of relief. The possibility of curing the venereal disease without mercury by no means establishes the propriety of abandoning this remedy, any more than its unfitness for certain states of the same disease ought to be a reason for not availing ourselves of its superior utility in others.

Mercury taken into the stomach in its metallic state has no action on the body, except what arises from its weight or bulk. It is not poisonous, as was vulgarly supposed, but perfectly inert. But in its various states of combination it produces certain sensible effects. It is a powerful and general stimulant, quickening the circulation, and increasing all the secretions and excretions. According to circumstances, the habit of the patient, the temperature in which he is kept, the nature of the preparation, and the quantity in which it is exhibited, its effects are indeed various. Sometimes it more particularly increases one secretion, sometimes another; but its most characteristic effect is the increased flow of saliva which it generally excites if given in sufficient quantity.—(*Edinb. Dispensatory.*)

From the writings of Theodoric it appears that mercury was employed in the practice of medicine and surgery as early as the thirteenth century. But its use in venereal cases was first mentioned in a tract by Almenar, published in 1516.—(See *Thompson's Dispensatory*, *p.* 205, *edit.* 2.)

It has been said that the efficacy of mercury in curing the venereal disease was an accidental discovery; but it seems more probable that the good effects which it produced in cutaneous diseases first led to the trial of it in venereal cases, which, being frequently attended with eruptions, ulcers, &c. seemed to present an analogy to the affections, in which mercury had already been found successful.

In the times immediately following the supposed origin of the venereal disease, practitioners only ventured to employ this remedy with timorous caution, so that, of several of their formulæ, mercury scarcely composed a fourteenth part, and either on this account, or some difference in the disease itself at that period from what is now remarked, few cures were effected. On the other hand, the empirics who noticed the little efficacy of these small doses ran into the opposite extreme, and exhibited mercury in quantities so large, and with so little care, that most of their patients were suddenly attacked with violent salivations, frequently attended with very dangerous and even fatal symptoms; or such as after making them lose their teeth, left them pale, emaciated, exhausted, and subject, for the rest of their lives, to tremblings, or other more or less dangerous affections. From these two very opposite modes of practice there originated such uncertainty respecting what could be expected from mercury, and such fears of the consequences which might result from its employment, that every plan was eagerly adopted which offered the least chance of cure without having recourse to this mineral.

A medicine, however, so powerful, and whose salutary effects had been watched by attentive practitioners amid all its inconveniences, could not sink into oblivion. After efforts had been made to discover an equally efficacious substitute for it, and it had been seen how inferior other means were, on which the highest praises had been lavished, the attempts to extend its utility were renewed. A medium was pursued between the two timid methods of those physicians, who had first administered it, and the inconsiderate boldness of empirics. Thus the causes from which both parties failed, were avoided; the character of the medicine was revived in a more durable way, and from this period, its reputation has always been maintained.

The renowned Paracelsus first taught practitioners, that mercury might be given internally with safety; for, before he set the example, it had only been externally employed, in three manners. The first was in the form of an ointment or liniment; the second, as a plaster; and the third, as a fumigation.

The basis of the ointment or liniment was quick silver, which was blended by means of trituration, with hog's lard, goose's fat, &c. and composed scarcely

one-sixth or one-eighth of the whole; a proportion, however, much greater than what had been at first employed. But from a fear that the mineral might prove hurtful to the nerves, by the cold property which they fancied it to possess, and that it might occasion numbness, tremblings, or palsies, they combined with it a multitude of ingredients of a warm aromatic nature, or supposed to possess such; for example, oil of camomile, sesame-seeds, aniseeds, the roots of zedoary, the florentine iris, and a thousand other substances, which were incorporated with the ointment. The members, joints, and the whole of the body, except the head, belly, and chest, were rubbed with this composition; and the frictions were repeated at suitable intervals, until obvious signs of salivation appeared.

The ingredients of the plasters resembled those of the ointments, only they contained less fat, for which was substituted a sufficient quantity of wax, to give them a proper consistence. This composition was applied to the skin, and the whole body was covered with it, excepting the parts on which it was not usual to put ointment. The plastors were kept on till salivation began.

The fumigations were made with quicksilver, triturated with turpentine or saliva, or else with cinnabar. These substances were mixed with fatty or resinous ores, such as myrrh, nutmeg, &c., and all the ingredients being reduced to powder, were made into a paste, with a sufficient quantity of turpentine or gum tragacanth. The patient was then placed in a box made on purpose, or under a little kind of tent, out of which the head was generally allowed to protrude. A chafing-dish, containing burning coals, was placed near his feet, and every now and then bits of mercurial paste were thrown into the vessel. The patient was left exposed to the fumes, which arose until he broke out in a profuse perspiration, which they took great pains to keep up and increase, by putting him into a warm bed, loading him with bedding, for about two hours, after which he was rubbed quite dry and given some food. This plan was persisted in every day, till a salivation was produced, which was kept up as long as necessary. The method of fumigation is described by Astruc, and particular preparations, and apparatuses for the purpose, have been since recommended by Lalonette in France, and, more recently, by Abernethy in England.

Of the three methods which have just been described, only the first is at present much in use, and even this is considerably altered. It was found, not only that mercurial plasters caused heat, redness, itching, and disagreeable eruptions, but that the method was exceedingly slow and uncertain. Hence, plasters are now only used as topical discutient applications.

Fumigations, considered as the only means of cure, fell also into discredit, because, although they formed a method of applying mercury in a very active manner, they were, as anciently managed, liable to several objections. In this way, it was next to impossible to regulate the quantity of mercury used, which varied according to the greater or less activity of the fire, the position of the patient, and other circumstances. The effect of the vapour on the organs of respiration also frequently proved very oppressive; and mercury, applied in the way of fumigation, more frequently occasioned tremblings, palsies, &c. than in any other manner. In Mr. Abernethy's mode, however, fumigation is, under certain circumstances, not only an eligible, but the very best way of affecting the constitution.

Frictions with ointment have always been regarded as the most efficacious. They have undergone considerable change, and by being rendered more simple, have been greatly perfected. All the warm aromatic substances have been retrenched from the ointment, not only as useless, but as irritating and inflaming to the skin. In modern times, the proportion of mercury to the fat has also been very much increased.

GENERAL REMARKS ON THE ADMINISTRATION OF MERCURY, ITS OCCASIONAL CONSEQUENCES, ETC.

With regard to the preparations of the medicine, and the modes of applying it, we are to consider two things: first, the preparation and mode attended with the least trouble, or inconvenience to the patient; and, secondly, the preparation and mode of administering it, that most readily conveys the necessary quantity into the constitution. Mercury is carried into the constitution in the same way as other substances, either by being absorbed from the surface of the body, or that of the alimentary canal. It cannot, however, in all cases, be taken into the constitution in both ways; for sometimes the absorbents of the skin will not readily receive it, at least, no effect is produced, either on the disease or constitution, from this mode of application. In this circumstance, mercury must be given by the mouth, although the plan may be very improper in other respects, and often inconvenient. On the other hand, the internal absorbents sometimes will not take up the medicine, or, at least, no effect is produced on the disease, or the constitution.

In such cases, all the different preparations of the medicine should be tried; for sometimes one succeeds when another will not. In some cases, mercury seems to have no effect, either applied outwardly, or taken into the stomach. Many surfaces seem to absorb mercury better than others; such are probably all internal surfaces and sores. Thirty grains of calomel, rubbed in on the skin, have not more effect than three or four taken by the mouth. Dressing small ulcers with red precipitate sometimes causes a salivation.—(See *Hunter on the Venereal Disease*, *p.* 335, 336.)

Besides the practicableness of getting the medicine into the constitution in either way, it is proper to consider the easiest for the patient, each mode having its convenience and inconvenience, depending on the nature of the parts to which it is applied, or on certain situations of life at the time. Hence, it should be given in the way most suitable to such circumstances.

In many, the bowels can hardly bear mercury at all, and it should then be given in the mildest form possible, conjoined with such medicines as will lessen or correct its violent local effects, although not its specific ones on the constitution.

When mercury can be thrown into the constitution with propriety by the external method, it is preferable to the internal plan, because the skin is not nearly so essential to life as the stomach, and therefore is capable in itself of bearing much more than the stomach. The constitution is also less injured. Many courses of mercury would kill the patient, if the medicine were only given internally, because it proves hurtful to the stomach and intestines, when given in any form, or joined with the greatest correctors. Every one, however, has not opportunities of rubbing in mercury, and is therefore obliged, if possible, to take it by the mouth. —(*Hunter*, *p.* 338.)

Mercury has two effects; one as a stimulus on the constitution and particular parts; the other as a specific against a diseased action of the whole body, or of parts. The latter action can only be computed by the disease disappearing.

When mercury is given in venereal cases, the first attention should be to the quantity, and its visible effects in a given time, which, when brought to a proper pitch, are only to be kept up, and the decline of the disease to be watched; for by this we judge of the invisible or specific effects of the medicine, and know what variation in the quantity may be necessary. The visible effects of mercury affect either the whole constitution, or some parts capable of secretion. In the first, it produces universal irritability, making it more susceptible of all impressions. It quickens the pulse, increases its hardness, and occasions a kind of temporary fever. In some constitutions, it operates like a poison; while, in others, it produces a kind of hectic fever, that is, a small, quick pulse, loss of appetite, restlessness, want of sleep, and a sallow complexion, with a number of consequent symptoms; but such effects commonly diminish on the patient becoming a little accustomed to the medicine. Mercury often produces pains like those of rheumatism, and nodes of a scrofulous nature.—(*Hunter*, *p.* 339, 340.)

The quantity of mercury to be thrown into the constitution for the cure of any venereal complaint, must be proportioned to the violence of the disease. However, we are to be guided by two circumstances, namely, the time in which any given quantity is to be thrown in, and the effects it has on some parts of the body, as the salivary glands, skin, or intestines. For mercury may be thrown into the same constitution in very different quantities, so as to produce the same ultimate effect; but the two very different quantities must also be in different times; for instance, one ounce of mercurial ointment, used in two days, will have more

effect upon the constitution, than two ounces used in ten. The effects of one ounce, used in two days, on the constitution and diseased parts, are considerable. A small quantity, used quickly, will have equal effects to those of a large one employed slowly; but, if these effects are principally local, that is, upon the glands of the mouth, the constitution at large not being equally stimulated, the effect upon the diseased parts must be less, which may be known by the local disease not giving way in proportion to the effects of mercury on some particular part. If it is given in very small quantities, and increased gradually, so as to steal insensibly on the constitution, a vast quantity at a time may at length be used, without any visible effect at all.—(*Hunter, p.* 341.)

These circumstances being known, mercury becomes a much more efficacious, manageable, and safe medicine, than it was formerly thought to be; but unluckily, its visible effects upon the mouth and the intestines are sometimes much more violent than its general effect upon the constitution at large. These parts must therefore not be stimulated so quickly, as to hinder the necessary quantity of mercury from being used.

The constitution or parts are more susceptible of mercury at first than afterward. If the mouth is made sore, and allowed to recover, a much greater quantity may be thrown in a second time, before the same soreness is produced. However, anomalous cases occur, in which, from unknown causes, mercury cannot at one time be made to produce any visible effects; but afterward the mouth and intestines are all at once affected.—(*Hunter, p.* 342.)

Mercury occasionally attacks the bowels, and causes violent purging, even of blood. This effect is remedied by discontinuing the use of the medicine and exhibiting opium. At other times, it is suddenly determined to the mouth, and produces inflammation, ulceration, and an excessive flow of saliva. To obtain relief in this circumstance, purgatives, nitre, sulphur, gum-arabic, lime-water, camphor, bark, the sulphuret of potash, blisters, &c. have been advised. Mr. Pearson, however, does not seem to place much confidence in the efficacy of such means, and the mercury being discontinued for a time, he recommends the patient to be freely exposed to a dry cold air, with the occasional use of cathartics, Peruvian bark, and mineral acids, and the assiduous application of astringent gargles. "The most material objection (says Mr. Pearson), which I foresee against the method of treatment I have recommended, is the hazard to which the patient will be exposed of having the saliva suddenly checked, and of suffering some other disease in consequence of it.

"That the hasty suppression of a ptyalism may be followed by serious inconveniences, has been proved by Dr. Silvester (*Med. Obs. and Inq. vol.* 3), who published the cases of three persons, who had been under his own care; two of whom were afflicted with violent pains; and the third scarcely retained any food in her stomach for the space of three months. I have seen not only pains, but even general convulsions, produced from the same cause. But this singular kind of metastasis of the mercurial irritation does not appear to me to owe its appearance to simple exposure to cold and dry air; because, I have known it occur in different forms, where patients continued to breathe a warm atmosphere, but used a bath, the water of which was not sufficiently heated. Cold liquids, taken in a large quantity into the stomach, or exposure of the body to cold and moisture, will also prove extremely injurious to those who are fully under the influence of mercury; whereas breathing a cool air, while the body is properly covered with apparel, has certainly no tendency to produce any distressing or dangerous consequences.

"If, however, a suppression of the ptyalism should be occasioned by any act of indiscretion, the remedy is easy and certain; it consists only in the quick introduction of mercury into the body so as to produce a soreness of the gums, with the occasional use of a hot bath."—(*Pearson on the Effect of various Articles in the Cure of Lues Venerea, ed.* 2, *p.* 163, 164.)

Mercury, when it falls on the mouth, produces, in many constitutions, violent inflammation, which sometimes terminates in mortification. In these habits, great caution is necessary. The ordinary operation of mercury does not permanently injure the constitution; but occasionally, the impairment is very material; *mercury may even produce local disease, and retard the cure of chancres, buboes, and certain effects of the lues venerea, after the poison has been destroyed.*—(*Hunter, p.* 342.)

From mercury occasionally acting on the system as a poison, quite unconnected with its agency as a remedy, and neither proportionate to the inflammation of the mouth, nor the actual quantity of the mineral absorbed, Mr. Pearson noticed that one or two patients in general died suddenly every year in the Lock Hospital. The morbid state of the system, which tends to the fatal event during a mercurial course, is named by Mr. Pearson *erethismus*, and is characterized by great depression of strength, a sense of anxiety about the præcordia, irregular action of the heart, frequent sighing, trembling, a small, quick, and sometimes an intermitting pulse, occasional vomiting, a pale contracted countenance, a sense of coldness; but the tongue is seldom furred, and neither the vital nor natural functions are much disordered; a statement, however, according to my notions, not very consistent with the alleged irregular action of the heart. They who dié suddenly of the mercurial erethismus have frequently been making some little exertion just before. To prevent the dangerous consequences of this state of the system, the use of mercury must be discontinued, whatever may be the stage, extent, or violence of the venereal symptoms. The patient should be directed to expose himself freely to a dry and cool air, in such a manner as shall be attended with the least fatigue, and he should have a generous diet. In this manner, patients often recover sufficiently in ten or fourteen days, to resume the use of mercury with safety. In the early stage, the mercurial erethismus may often be averted by leaving off the mercury, and giving the mistura camphorata with large doses of ammonia. When the stomach is unaffected, sarsaparilla sometimes does good.—(*Pearson, p.* 154, *&c.*)

Occasionally the use of mercury brings on a peculiar eruption, which has received the several names of *hydrargyria, mercurial rash, eczema mercuriale, eczema rubrum, lepra mercurialis, mercurial disease*, and *erythema mercuriale.*

"Eruptions of various kinds are very common symptoms of syphilis, but a very unusual effect of mercury Therefore, until the real nature of this erythema was lately discovered, whenever it occurred in patients undergoing a mercurial course for syphilitic complaints, it was naturally enough considered as an anomalous form of lues venerea. The mercury was consequently pushed to a greater extent, in proportion to the violence of the symptoms; and from the cause of the disease being thus unconsciously applied for its removal, it could not fail to be aggravated and hurried on to a fatal termination. The observation of this fact, conjoined with another of less frequent occurrence, namely, that a similar eruption did sometimes appear in patients using mercury for other complaints, and in whom no suspicion of syphilis could be entertained, at last led some judicious practitioners in Dublin to the important discovery, that the eruption was entirely an effect of mercury, and not at all connected with the original disease. This discovery was not published till 1804."—(*M'Mullin in Edinburgh Medical and Surgical Journal, No.* 5.) Mr. Pearson states, however, that he has been acquainted with the disease ever since 1781, and has always described its history and treatment in his lectures since 1783.

The eruption is attended with more or less indisposition, is not confined to either sex, or any particular constitution, and seems to be equally produced by mercury applied externally, and by any of its preparations taken inwardly. Mr. Pearson has never seen it in subjects above fifty; and he says, its occurrence is more common about eight or ten days after beginning a mercurial course.—(*P.* 166.)

Dr. M'Mullin has described three distinct stages of the erythema mercuriale. "The first stage commences with languor, lassitude, and cold shiverings; these symptoms are succeeded by increased temperature of the body, quick pulse, nausea, headache, and thirst. The patient is troubled with a dry cough, and complains of difficult respiration, anxiety, and sense of stricture about the præcordia. The tongue is usually moist, and covered with a white glutinous slime: it sometimes appears clean, and brightly red in the centre, while the margins remain foul. The skin feels unusually hot and itchy, with a sense of pricking, not

unlike the sensation experienced from the application of nettles. The belly is generally costive; but a diarrhœa is often produced by very slight causes.

"On the first or second day, an eruption most commonly shows itself, the colour of which is either dark or bright red: the papulæ are at first distinct and elevated, resembling very much those in rubeola. Sometimes, but rarely, the eruption appears like urticaria, and in such instances the disease is observed to be very mild. The papulæ very speedily run together, in such a manner as to form a suffused redness, which disappears on pressure. In most cases, it begins first on the scrotum, inside of the thighs, forearm, or where mercurial friction has been applied, and the integuments of the parts affected become much swollen. There have so been observed instances, where an eruption of a purplish colour, and unaccompanied by papulæ, has diffused itself suddenly over the entire body. This, however, may be considered as uncommon. In every instance which came under my observation, it was confined at first to a few places, and from thence gradually extended, until the different portions of the eruption had united, and the papulæ were also rough. But in those cases which resemble urticaria, a number of minute vesicles, which contain a serous fluid, appear, from the commencement, interspersed among the papulæ. Contrary to what happens in most diseases accompanied with cutaneous affections, the febrile symptoms are much aggravated, and continue to increase after the eruption has been completed. The pulse in general beats from 120 to 130 in a minute, the thirst continues urgent, and the patient, extremely restless, seldom enjoys quiet sleep. When the eruption has continued in this manner for a certain period, the cuticle begins to peel off in thin, whitish, scurfy exfoliations, not unlike those observed in rubeola. This desquamation has not been attended to by Dr. Moriarty or Mr. Alley, if they have not, by giving the same name to the decrustation which occurs in the last stage, confounded both together. It commences in those places where the eruption first made its appearance, and in this order spreads to other parts. About this period the fauces become sore, the tongue swells, and the eyes appear somewhat inflamed.

"The duration of this stage is very various; sometimes it continues from ten to fourteen days, and in other cases it terminates in half that time. When the disease has appeared in its mildest form, the patient recovers immediately after the desquamation, a new cuticle having formed underneath; but, if severe, he has only experienced the smallest part of his sufferings, and the skin now assumes a new appearance, which I have considered as the second stage.

"The skin at this period appears as if studded with innumerable minute vesicles, which are filled with a pellucid fluid. These vesicles may be expected, if the patient, at the close of the first stage, complains of increased itching, and sense of burning heat, in those parts from which the cuticular exfoliations have fallen. They remain sometimes for a day or two, but are most commonly burst, immediately after their formation, by the patient rubbing them, in order to relieve the troublesome itchiness with which these parts are affected. They discharge a serous, acrimonious fluid, which possesses such a very disagreeable odour as to induce nausea in the patient himself, and those who approach near his bedside. The odour is so peculiar that it can easily be recognised by any person who has once experienced it.

"This fluid is poured out most copiously from the scrotum, groin, inside of the thighs, or wherever the skin forms folds, and the sebaceous glands are most numerous. The serous discharge from these minute vesicles forms, with the cuticle, an incrustation, which may be considered as the third or last state.

"These crusts are generally very large, and, when detached, retain the figure of the parts from which they have fallen. Their colour is yellowish; but sometimes appears dark and dirty. This period of the disease might be termed, I think, with much propriety, the stage of *decrustation*, in order to distinguish it more fully from the *desquamation*, which has been already noticed. From the use of the last two terms indiscriminately, those who have described the disease have introduced into their descriptions a degree of confusion which has caused its progress not to be well understood. When this stage appears, the fauces become more affected, the eyes intolerant of light, and the tarsi tender, inflamed, and sometimes inverted. The crusts formed on the face, as in other parts of the body, before falling off, divide asunder, so as to leave cracks and fissures, which produce a hideous expression of countenance; and the eyelids are also, from the general swelling of the face, completely closed. The back and hairy scalp are last affected, and, even in very severe cases, these parts are sometimes observed to escape entirely. The patient, while in this state, is compelled to desist from every kind of motion, on account of the pain which he experiences on the slightest exertion, and which he describes as if his flesh were cracking. The crusts also fall off in such abundance, that the bed appears as if strewed with the cones of hops. While the eruption is only making its appearance in one place, another part may have arrived at its most advanced form; so that all the different stages of the disease may be present at one time in the same individual. It is attended with typhus through its entire course; but it is very curious to observe, that the appetite for food, in most cases, remains unimpaired, and sometimes is even voracious. This circumstance was particularly remarkable in a patient who laboured under the disease, in its worst form, for the space of three months, in the Royal Infirmary of Edinburgh; for double the usual hospital allowance of food was scarcely sufficient to satisfy his hunger. When the catarrhal symptoms have continued during the progress of the complaint, they are at this advanced period particularly aggravated; the anxiety and pain of the breast are also very severe, attended with cough, and bloody expectoration, and the patient always feels languid and dejected. The pulse becomes frequent, feeble, and irregular, the tongue black and parched, and at length diarrhœa, delirium, convulsions, gangrene of the surface of the body, and death, supervene. In its mild form it only goes through the first stage, and terminates, as we have already stated, in a few days, by a slight desquamation. But when severe, it is often protracted more than two months, every stage of the eruption continuing proportionably longer; and when, in this manner, it has run its course, it repeatedly breaks out on the new surface, and passes through the same stages."—(*M'Mullin in Edinb. Med. and Surg. Journal, No.* 5.)

The remote cause is the employment of mercury. Dr. M'Mullin is inclined to believe with Dr. Gregory, that the application of cold to the body while under the action of mercury, is absolutely necessary for its production; an opinion strengthened by the constant prevalence of catarrhal symptoms. However, Mr. Pearson thinks that cold has no concern in bringing on the complaint in patients under the influence of mercury. At the same time it merits particular attention, that the disease is not exclusively occasioned by mercury, either in its general or more partial attacks; it has been observed to follow exposure to cold, and to recur in the same individual at regular intervals, without any obvious or adequate cause.—(*Bateman's Synopsis, p.* 256, *ed.* 3; *Rutter in Edin. Med. and Surg. Journ. vol.* 5, *p.* 143; *Marcet in Med. Chir. Trans. vol.* 2, *art.* 9.)

In the early stage, Mr. Pearson recommends small doses of antimonial powder, with saline draughts, or the ammonia acetata. A gentle purgative should be given every three or four days, and opium to procure sleep. The latter medicine sometimes does most good, when joined with camphor, or Hoffman's anodyne liquor. Sarsaparilla and bark may be given when the discharge is no longer ichorous, and the tumefaction has subsided. Vitriolic acid has seemed to give relief. The diet may be light and nutritive, without fermented liquors, however, till the desquamation has somewhat advanced. Frequent use of the warm bath, and often changing the patient's linen and sheets, which soon become stiff and rough with the discharge, afford much benefit. If the warm bath cannot be had, Mr. Pearson advises washing the body very tenderly with warm water-gruel; he also covers parts from which the cuticle is detached, with a mild cerate, and renews the application twice a day.—(*P.* 178.)

Dr. M'Mullin advises the immediate discontinuance of mercury; the removal of the patient from wards where this mineral is in use; emetics and diaphoretics; but, on account of the very irritable state of the bowels, he says, antimonials are hardly admissible and that

when purgatives are indicated, only the mildest ones, such as ol. ricini, sulphate of magnesia, &c. ought to be given. He advises mucilaginous draughts with opium for relieving the soreness of the fauces. In the second stage, the cold infusion of bark with aromatics and opium, or, what is more praised, wine, porter, &c. To relieve the ophthalmia tarsi, the unguentum oxidi zinci, and to appease the painful sensation of the skin cracking, the linimentum calcis, which should be liberally applied as soon as crusts appear.

Dublin*, 1804: *also Observations on the Hydrargyria, or that Vesicular Disease arising from the Exhibition of Mercury, 4to. Lond.* 1810. *A Description of the Mercurial Lepra, by Dr. Moriarty, 12mo. Dublin*, 1804. *Spens and M'Mullin, in Edinburgh Med. and Surgical Journal, Nos.* 1 *and* 5. *Pearson on Lues Venerea, edit.* 2. *Bateman's Synopsis, p.* 256, *&c. ed.* 3.

Frictions with Mercurial Ointment.

No metal acts in its pure metallic state; it must first be more or less combined with oxygen. The mercury contained in the unguentum hydrargyri becomes in a certain degree oxydated, when triturated for the purpose of blending it with the fat. The metal, however, in mercurial ointment, is in the most simple and least combined form of all its preparations, and hence it not only generally operates with more mildness on the system, but with more specific effect on the disease. Various salts of mercury, when given internally, operate more quickly than mercurial frictions; yet some practitioners, erroneously, I believe, do not confide in any internal preparations for curing the venereal disease, particularly when the virus has produced effects in consequence of absorption. We shall only just mention in this part of the work, that rubbing in mercurial ointment is the mode of affecting the system with mercury, which is generally considered to agree best with most constitutions, and to act with most certainty on the venereal disease. The plan, however, on account of its uncleanliness, is frequently omitted.

Mercurial Fumigations.

We have mentioned this method as being one of the most ancient plans of affecting the constitution with mercury, and Lalonette and Abernethy have stated circumstances in its favour, which certainly render it sometimes a very eligible mode. The latter is of opinion, that if the peculiar advantages of mercurial fumigation were generally known to practitioners, they would be much more frequently employed. The advantages of the method consist in its affecting the constitution when other means have failed, and in producing its effects in a much shorter time, than any other mode requires. How desirable this celerity of operation must often be when venereal ulceration is making great ravages in the palate, throat, &c. it is needless to insist upon. In patients who have not strength to rub in ointment, and whose bowels will not bear the internal exhibition of mercury, the mode of fumigation may prove of great service.

"In the year 1776, the Chevalier Lalonette, a physician at Paris, laid before the public an account of a new mode of mercurial fumigation, free from the inconveniences of former ones, and which in the space of thirty-five years he had successfully employed in more than four hundred cases that had resisted all the ordinary methods of cure. His method consisted in enclosing the patient, previously undressed, in a kind of box resembling a sedan-chair, with an opening at the top to let out the head, and another at the bottom, to which was fitted a small grate or furnace, having in it a heated iron for converting the mercurial remedy into fume. The preparation he made use of was a kind of calomel, which, by repeated sublimation from iron filings, was so far deprived of its muriatic acid, as to be in part reduced into running quicksilver; and while it possessed considerable volatility, was perfectly unirritating. Some of this powder being strewed upon the hot iron placed below, was immediately converted into smoke, which surrounded the patient's body, and after some time settled on his skin in the form of a white and very fine calx of quicksilver: a complete dress, having its inner surface fumigated with the same powder, was then put on. The remedy being thus generally applied to the mouths of the cutaneous absorbents, soon got admission into the circulating fluids, and the constitution became thereby more speedily affected than by any process known before.—(*Abernethy's Surgical and Physiological Essays, part* 3.)

As the fumigating powder used by M. Lalonette was very operose, and consequently an expensive preparation, and appeared to have no advantage over one made by abstracting the muriatic acid from calomel by means of ammonia, Mr. Abernethy employed the latter, which was prepared in the following manner: Two drachms of liquor ammoniæ are added to six ounces of distilled water, and four ounces of calomel are thrown into this liquor, and shaken up with it; the powder is afterward separated by a filter and dried.

The powder thus obtained is of a gray colour, and contains a good deal of quicksilver in its metallic state, which of course is extremely volatile, but becomes oxydated when raised into fume, and afterward condensed into a white subtile powder.

In local disease of the joints, such for instance as a thickened state of the synovial membrane, and in sarcomatous enlargements of the breast in women, the late Mr. Sharpe and Sir C. Blicke were accustomed to direct fumigated stockings or under-waistcoats to be worn, by which these complaints were relieved and the constitutions of the patients affected, without the trouble and unpleasantness arising from the use of the common mercurial ointment.—(See *Abernethy's Surgical and Physiological Essays, part* 3.)

Mr. Pearson procured Lalonette's machine, and made a considerable number of experiments to determine the comparative advantages of this method and mercurial frictions. He found that the gums became turgid and tender very quickly, and that the local appearances were sooner removed, than by the other modes of introducing mercury into the system; but that it soon brought on debility, a rapid and premature salivation, and, of course, that the medicine could not be steadily continued. This gentleman concludes, that when checking the progress of the disease suddenly is an object of great moment, when the body is covered with venereal ulcers, or when the eruptions are large and numerous, so that there scarcely remains a surface large enough to absorb the ointment, the vapour of mercury will be advantageous. But he thinks it extremely difficult thus to introduce a sufficient quantity of mercury into the system to secure the patient from a relapse, and therefore the plan by no means eligible as a general practice. The vapour of mercury, he says, is singularly efficacious, when applied to venereal ulcers, fungi, and excrescences; but this plan requires an equal quantity of mercury to be given in other ways, as if the local application itself were not a mercurial one.—(*Pearson on Lues Venerea, p.* 145, *&c.*) This last observation is certainly not correct.

For the purpose of fumigating sores, the hydrargyri sulphuretum rubrum is commonly used. Ulcers and excrescences about the pudendum and anus in women are said to be particularly benefited in this way; and in these cases the fumes are most conveniently applied by placing a red-hot heater at the bottom of a night-stool pan, and after sprinkling on it a few grains of the red sulphuret of quicksilver, placing the patient on the stool. On other occasions, a small apparatus sold at the shops, is used, which enables the surgeon to direct the fumes through a funnel against the ulcer in any situation.

Though mention has just been made of *venereal* excrescences, I am of opinion, with Mr. Abernethy, that it is very questionable whether any are ever really of this nature. I know that many excrescences and verrucæ about the anus and parts of generation, diminish and are cured by a course of mercury. This is the only argument in favour of their being venereal; for when tied, cut off, or made to fall off by stimulating them with pulv. sabinæ and the subacetate of copper, or the acetic acid, they are as effectually cured as if mercury had been given. In the military hospital at Cambray, I remember a man whose scrotum was covered with watery excrescences, some of which were of considerable size. Mr. Booty, assistant staff surgeon, prescribed mercury, by which they were certainly cured with surprising expedition. In this particular case I think the plan of treatment adopted was the best, because on account of the number of excrescences, and the situation of some of them at the lower

and back part of the scrotum, it would have been difficult to have treated them altogether by local applications.

PREPARATIONS FOR INTERNAL EXHIBITION.

When it is wished to excite a salivation quickly, and mercurial ointment alone will not produce this effect, or cannot be employed, and when fumigations are not convenient or agreeable, the hydrargyri oxydum rubrum is often prescribed. The common dose is a grain, which may be increased to two, a day. It is apt, however, to disagree with the stomachs and bowels of many patients; an inconvenience sometimes obviated by conjoining the preparation with opium.

At present the hydrargyrus cum creta is rarely or never prescribed for the cure of the venereal disease. But it is frequently prescribed as a mild alterative for children in doses of from gr. v. to gr. x. twice a day, blended with any viscid substance.

The oxymuriate of mercury (corrosive sublimate) was a medicine highly praised for its antisyphilitic virtues by the celebrated Van Swieten, and indeed there is no doubt that like other preparations of mercury it possesses such qualities. It retains great reputation even now, and probably will always do so. However, like the red oxide, it sometimes deranges the stomach and bowels. Some surgeons are also reluctant to give it the same degree of confidence in respect to its power over syphilis, as they give to mercurial frictions. Mr. Pearson remarks, that "when the sublimate is given to cure the primary symptoms of syphilis, it will sometimes succeed, more especially when it produces a considerable degree of soreness of the gums, and the common specific effect of mercury in the animal system. But it will often fail of removing even a recent chancre; and where the symptom has vanished during the administration of corrosive sublimate, I have known a three months' course of that medicine fail to secure the patient from a constitutional affection. The result of my observations is that simple mercury, calomel, or calcined mercury are preparations more to be confided in for the cure of primary symptoms than corrosive sublimate. The latter will often check the progress of secondary symptoms very conveniently, and I think it is peculiarly efficacious in relieving venereal pains, in healing ulcers of the throat, and in promoting the desquamation of eruptions. Yet even in these cases, it never confers permanent benefit; for new symptoms will appear during the use of it; and on many occasions it will fail of affording the least advantage to the patient from first to last. I do sometimes, indeed, employ this preparation in venereal cases; but it is either at the beginning of a mercurial course, to bring the constitution under the influence of mercury at an early period, or during a course of inunction, with the intention of increasing the action of simple mercury. I sometimes also prescribe it after the conclusion of a course of frictions, to support the mercurial influence in the habit, in order to guard against the danger of a relapse. But on no occasion whatever do I think it safe to confide in this preparation singly and uncombined, for the cure of any truly venereal symptom."—(*Pearson on Lues Venerea.*)

The dose of oxymuriate is a quarter of a grain.

The following is a common mode of ordering it: ℞. Hydrargyri oxymuriatis. gr. i. Aquæ Nucis Moschatæ, ℥ij. Misce. Dosis uncia dimidia.

The submuriate of mercury (calomel) is not very much used by modern surgeons for the cure of the venereal disease. Sometimes, indeed, it is given in cases of gonorrhœa, both with the view of preserving the constitution from infection, and keeping the bowels regular. It is more extensively given as a purgative and an alterative, and for the cure of surgical diseases requiring the system to be slightly under the influence of mercury. It generally proves actively purgative, when more than two or three grains are given.

The most simple preparations of mercury have generally been deemed the most effectual in eradicating the venereal disease. The pilulæ hydrargyri are the most simple of the internal formulæ, being merely mercury triturated with mucilaginous or saccharine substances. Next to mercurial frictions, they are, perhaps, most frequently employed for the cure of the incipient form of the venereal disease, that is, while a chancre is the only complaint. They are also very commonly given in all stages of the disease, to aid mercurial frictions in bringing the system under the influence of the specific remedy. Ten grains of the mass kept for these pills is the usual dose. When they purge, opium will sometimes prevent this effect.—(See *Venereal Disease.*)

Mercury is employed both constitutionally and locally in numerous surgical cases; for the removal of indolent thickenings and indurations of the parts; for the relief of porrigo, herpetic diseases, tetanus, hydrops articuli, iritis, and a multitude of other affections, which need not here be specified.

MEROCELE. (From μηρος, the thigh, and κηλη, a tumour.) A femoral or crural hernia.—(See *Hernia.*)

MEZEREON was recommended by Dr. A. Russell for a particular class of venereal symptoms, in the following terms: "The disease for which I principally recommend the decoction of the mezereon root as a cure, is the venereal node that proceeds from a thickening of the membrane of the bones. In a thickening of the periosteum, from other causes, I have seen very good effects from it; and it is frequently of service in the removal of those nocturnal pains with which venereal patients are afflicted; though in this last case, excepting with regard to the pain that is occasioned by the node, I own I have not found its effects so certain, as I at first thought I had reason to believe. I do not find it of service in the cure of any other symptom of the venereal disease."—(*Med. Obs. and Inq. vol. 3, p. 134, 195.*) Mr. Pearson, however, asserts unequivocally, that mezereon has not the power of curing the venereal disease in any one stage, or under any one form; and if the decoction should ever reduce the venereal node, yet there will be a necessity for taking mercury in as large quantity, and for as long a time, as if no mezereon had been exhibited. Cullen found this medicine of use in some cutaneous affections, but, excepting an instance or two of lepra, Mr. Pearson has very seldom found it possessed of medicinal virtue, either in syphilis, or the sequelæ of that disease, scrofula, or cutaneous affections.—(*Pearson on Lues Venerea, p. 55—59.*)

As the *possibility* of curing most forms of the venereal disease, not only without mercury, but without any internal medicines whatever, is now well established, it is difficult to know what degree of importance to attach to observations declaring certain articles of the materia medica efficient or inefficient in the cure of that disease; because, if it admit of a spontaneous cure, but will not get well when mezereon or any other particular medicine is exhibited, we are necessarily obliged to suppose that such medicine is worse than useless.

MODIOLUS. The crown or saw of a trepan.

MOLLITIES OSSIUM. A morbid softness of the bones, which become preternaturally flexible, in consequence either of the inordinate absorption of the phosphate of lime, from which their natural solidity is derived, or else of this matter not being duly secreted into their texture. The bones affected become specifically lighter.—(*Saillant, Hist. de la Soc. Royale de Med. t. 8.*) Dr. Bostock made some experiments, with the view of ascertaining the proportion of earthy matter in bones affected with mollities: he examined a dorsal vertebra of a woman, whose bones were found soft and flexible after her decease. In one part of the diseased bone, he found that the quantity of earthy matter only amounted to one-fifth of its weight, and, in another, only to one-eighth, while the proportion in healthy bones amounted to more than one-half of their whole weight.—(See *Med. Chir. Trans. vol. 4, and Wilson on the Bones and Joints, p. 253.*) In rickets, the bones yield and become distorted only by slow degrees, and retain their natural inflexibility; but in the present disease, they may be at once bent in any direction, and frequently admit of being readily divided with a knife. The mollities ossium is an exceedingly uncommon disease, and its causes are buried in obscurity. It is supposed, however, to depend upon some peculiar state of the constitution, and the individuals attacked with it have been remarked to be mostly about, or rather beyond the middle period of life (*J. Wilson, vol. cit. p 252*), and generally, if not always, women.—(*Neumann in Abhandl. der K. K. Josephs Acad. b. 2, p. 173. Portal Cours d'Anatomie, t. 1, p. 15.*) One instance, however, is reported, in which the patient was a young man, seventeen years of age.—(*Thomassin, in Journ. de Méd. t. 43, p. 222.*) Surgical writers have usually

considered mollities and fragilitas ossium as two distinct and different affections. Boyer thinks, however, that this point is by no means well established. He admits that there have been a few rare instances of mollities, where the bones were completely flexible, without any degree of fragility. But he contends, that in almost all the cases on record, the fragilitas and mollities have been combined. He regrets that bones, affected with fragility, have never been chemically and anatomically examined, particularly as there have been persons, who while living merely betrayed the symptoms of mollities ossium, yet in whom unsuspected fractures, evidently of long standing, were discovered after death; while other fractures also happened from the slightest causes during the examination of the same bodies.—(See *Boyer, Traité des Maladies Chir. t.* 3, *p.* 607—609.) The truth of these observations is well illustrated in the case reported by Mr. Wilson.—(*On the Bones, &c. p.* 254.) In the present place, I shall merely describe the pure mollities ossium, or that disorder of the bones in which they become completely flexible, and lose all their natural firmness. And in order to give an idea of the disorder, I shall quote the case of Madame Supiot. In the year 1747 she had a fall, which occasioned her to keep her bed for some time, and left great pain and weakness in her loins and lower extremities. In about a year and a half afterward, she began to perceive her left leg particularly affected. Along with this weakness, she had violent pains over her whole body, which increased after a miscarriage, and still more after a natural delivery, in the year 1751. She was now seized with startings, great inquietude, and such violent heats, that she was almost continually in a sweat, and could not bear the least covering, even in the coldest weather, and while her pains continually increased, she took notice that her urine precipitated a white sediment. Her pains abated on the appearance of the sediment, but she now observed that her limbs began to bend, and from this time the softness of them gradually increased till her death. In the month of April, 1752, the trunk of her body did not exceed 23 inches in length, the thorax was exceedingly ill formed, and the bones of the upper part were very much distorted; those of the lower part were considerably bent. At length the thigh-bones became so pliable, that her feet could easily be laid on each side of her head. The right side did not, till after some time, become so deformed as the left; but it was surprising to observe the alteration which daily took place, and the different figures assumed by the limbs, in consequence of the increased softness of the bones; so that when the sediment in the urine was considerable, the disease of the bones seemed to be at a stand, increasing considerably when it was suppressed. Besides this, she had violent pains, startings, difficulty of breathing, spitting of blood, and, lastly, a fever, with convulsions. She died in the beginning of November, 1752, and on dissecting her body, the following appearances were observed: 1. The muscles in general were of a very soft and pale consistence; the vastus externus fascialis, quadriceps, biceps, and external parts of the gracilis, were much shorter than in their natural state, and more firm and tense; while those on the opposite side were much elongated, thin, and very tender; in short, the whole muscular system had suffered more or less, according to the action of the muscles in her lifetime. 2. The bones were entirely dissolved, the periosteum remaining unhurt, so that they exhibited only the form of a cylinder. 3. The heart and principal blood-vessels, both veins and arteries, contained large black polypi, of a viscid consistence, and very unlike those usually found in dead bodies.

A case of softness of the bones is related by Mr. Gooch, but considerably different from the above, as it was attended with a remarkable fragility of them before they became soft. It likewise began with pains through the whole body, attended with feverish symptoms; but, after some weeks, these pains were confined chiefly to the legs and thighs, and they were not increased by pressure. This fragility of the bones does not appear to have been the case with Madame Supiot. In the month of June, 1749, Mr. Gooch's patient broke her leg in walking from her bed to a chair, and heard the bone snap. No callus was formed, though the fracture was instantly reduced, and treated by one of the best surgeons in her part of the country; but, instead of this, the bones began to grow flexible, and in a few months were so from the knee to the ankle. The disease still continued to increase, so that in a short time the other leg and thigh were affected in the same manner, after which both legs and thighs became œdematous, liable to excoriations, and discharged a thin yellow ichor. Scorbutic symptoms began to appear in the winter after the leg was broken, and her gums began to bleed. Tonic medicines were exhibited without any success, except that her menstruation was more regular, and her appetite and digestion were improved; but towards the end of her life, her breathing became difficult, the spine distorted, and a pain in the loins took place upon every motion of the vertebræ: and as her limbs were now quite useless, she was obliged to sit upright in bed. At last the ends of the bones on which she sat having become also very soft, spread much, and the ends of her fingers and thumbs, by frequent endeavours to raise herself, became also very broad, and the phalanges crooked. The flexibility of the bones gradually increased, and became more general, attended with a wasting of the flesh, and excessive difficulty of breathing. The menstrual flux totally ceased four months before her death; her legs, which were very anasarcous, and excoriated almost all over, became erysipelatous; but she retained her senses to the last. She expired suddenly, having talked in a composed manner concerning her miserable situation and approaching end, only a few moments before her death.

On examining the body, she was found to have lost two feet two inches of her natural stature. The heart and lungs appeared sound, but had been much confined, principally by the liver, which was enlarged in an extraordinary degree; it was not however, scirrhous, nor in any other way diseased. The spleen was very small, and the mesentery had one large scirrhous gland. All the bones except the teeth were softened, so that scarcely any of them could resist the knife; but those of the lower extremities were the most dissolved, being changed into a kind of parenchymous substance, like soft dark-coloured liver, without any offensive smell. So completely, indeed, were they decomposed, that the knife met with less resistance in cutting through them than sound muscular flesh, though some bony lamellæ were here and there to be met with, but as thin as an egg-shell. The most compact bones, and those which contained the greatest quantity of marrow, were the most dissolved; and it was observable that the dissolution began internally, for the bony laminæ remained here and there on the outside and nowhere else. The periosteum was rather thicker than ordinary, and the cartilages thinner; but not in a state of dissolution. The bones were found to contain a great quantity of oily matter and little earth. No cause could be assigned for the disease; and in the case of Madame Supiot, the one assigned, viz. that of her eating too much salt, seems totally inadequate to explain the origin of the disorder. All the cases of mollities ossium on record have proved fatal, and no means of cure are yet known.

For additional observations connected with this subject, refer to *Fragilitas Ossium* and *Rickets*. Boyer and Richerand treat of mollities ossium and rickets, as one and the same disease. But as Mr. Wilson observes, the first differs from rickets in attacking people of middle age or rather older, and not particularly children; and it differs also in the change produced in the bones themselves, which, when dried, do not appear as if they had been long steeped in weak acid, with their animal part nearly unchanged; but both the phosphate of lime and the animal matter appear to have been absorbed, so as to leave mere shells, which are also softer than natural bones of the same thickness. Mr. Wilson farther informs us, that large cavities are met with in the substance of the bones, and sometimes communicate with the soft parts surrounding them. In some of these cavities is contained oily matter, like boiled marrow; and in others, masses of coagulated blood, and a soft inorganic animal substance.—(*J. Wilson on the Bones, &c. p.* 253. *Acrel, Diss. MONOCULUS. (From *μονος*, single, and *oculus*, the eye.) A bandage formerly applied to the fistula lachrymalis, and diseases of the eye. It consists of a single-headed roller, the end of which is to be put on the back of the neck, and one turn made over the forehead so as to meet the extremity of the bandage. The roller is then to descend under the ear of the side affected, and to pass obliquely over the cheek underneath the eye, and next over the root of the nose and the parietal bone, to the nape of the neck. The third turn of the roller is to overlap the second a little; the third, the fourth; making what the French call *doloires*; and the application of the bandage is completed by making turns round the head.

MORTIFICATION is of two kinds; the one without inflammation; the other preceded by it. To this last species of mortification, the terms *inflammatory, humid*, or *acute gangrene*, are often applied; while the second, or that which is not preceded by any or much inflammation, has been distinguished by the epithets *dry* or *chronic*, and sometimes *idiopathic*, when no cause for the origin of the disease can be assigned. According to Mr. Hunter, inflammation is an increased action of that power which a part naturally possesses; and, in healthy inflammations at least, it is probably attended with an increase of power. In cases, however, which are to terminate in mortification, there is no increase of power; but on the contrary, a diminution of it. This, when joined to an increased action, becomes a cause of mortification, by destroying the balance which ought to subsist between the power and action of every part. There are, besides, cases of mortification preceded by inflammation, which do not arise wholly from that as a cause: of this kind are the carbuncle and the slough formed in the small-pox pustule.—(*Hunter.*)

The first general division of mortification, therefore, is into two kinds; first, into the *inflammatory, humid*, or *acute*; and secondly, into the *dry* or *chronic*. But the disorder is also subdivided into many species, which are determined by the nature of their particular exciting causes, as will be presently detailed.

However, it is remarked, that acute or rapid mortifications are not necessarily humid, as the slough from the application of caustic potassa proves, and the converse also is true in some cases of sphacelus scnilis.—(*James on Inflammation, p.* 96.) Mr. Guthrie also asserts, that mortification from wounds and external injuries may be either humid or dry, or of both kinds together, where the circumstances are particular.—(*On Gun-shot Wounds, &c. p.* 122, *ed.* 2.) The doctrine that any case of mortification is entirely without inflammation, has sometimes been deemed questionable; and Mr. James expresses his belief that the disorder is generally preceded by inflammation, and invariably *accompanied* with some degree of it. And, says he, "whether mortification be a consequence of inflammation or not, it may, perhaps, with reason be considered as standing in the same relation to inflammation as adhesion, suppuration, or ulceration; they may all be preceded by a high degree, or it may be scarcely sensible."—(*P.* 84, 85.)

When any part of the body loses all motion, sensibility, and natural heat, and becomes of a brown, livid, or black colour, it is said to be affected with *sphacelus*, that is, complete mortification. As long as any sensibility, motion, and warmth continue, the state of the disorder is termed *gangrene*. This word is here made use of to signify only a degree of sphacelus, or rather the process by which any local disorder falls into the state of complete mortification. Many authors use both terms synonymously; but it is to be observed, that gangrene does not invariably end in sphacelus; nor is the latter always preceded by the former.—(*Richter, Anfangsgr. der Wundarzn. b.* 1, *kap.* 3.) There are some surgical writers, who make the distinguishing circumstances of sphacelus to be the extension of the disorder to the bones as well as the soft parts.—(*Lassus, Pathologie Chir. t.* 1, *p.* 30, *ed.* 1809.)

At present, however, this last application of the term sphacelus is never made; for, as Mr. Pearson has rightly observed, the distinctions "which are founded merely upon the parts that suffer, or upon the profundity to which the disease has penetrated seem inadequate and useless."—(*Principles of Surgery, p.* 115, *ed.* 2.) The manner in which Dr. J. Thomson views the subject, may be considered as coinciding with the general sentiments of the best modern surgeons. "I shall employ the term *gangrene* (says he) to express that state of mortification in inflamed parts, which precedes the death of the part; a stage in which there is a diminution, but not a total destruction of the powers of life; in which the blood appears to circulate through the larger vessels; in which the nerves retain a portion of their sensibility; and in which, perhaps, the part affected may still be supposed to be capable of recovery. The word *sphacelus* I shall use to denote the complete death or mortification of a part; that state, in which the powers of life have become extinct; in which the blood ceases to circulate; and in which the sensibility of the nerves is lost, whether the dead or mortified part has or has not become actually putrid, or shown any tendency to separate and fall away from the living and sound parts. Putrefaction, or the spontaneous process by which animal bodies are decomposed, is an accidental, and not necessary effect of the state of mortification. It takes place at very different periods, after the death of particular parts; and these periods, it may be remarked, are always regulated, not only by external circumstances, such as the humidity and temperature of the atmosphere, but also by the peculiar structure and morbid conditions of the animal texture, or organ, in which the putrefaction occurs. The term sphacelus has, I know, been employed to express that a part is not only completely dead, or mortified, but also that that part has become putrid, and is in a state of separation from the surrounding and living parts. But as putrefaction is not a necessary or immediate consequence of mortification or partial death in animal bodies, this use of the term sphacelus is obviously improper."—(*On Inflammation, p.* 504.)

The causes of mortification are either internal or external. It is commonly taught in the medical schools on the continent, that the internal causes probably operate after the manner of a deleterious substance, which, being introduced into the circulation, occasions a putrefaction of the fluids.—(*Lassus, op. et loc. cit.*)—Boyer also professes a similar notion (see *Traité des Maladies Chir. t.* 1, *p.* 140), as well as Larrey in his account of *traumatic* gangrene; a statement which has drawn forth the criticisms of Mr. Guthrie. The doctrine is supported by no sort of proof, and may be considered as entirely hypothetical, if not decidedly erroneous. There are, indeed, as Boyer has noticed, some spontaneous mortifications, the primitive cause of which is not always well understood: an inflammation, apparently slight, may become gangrenous immediately it has made its appearance. In scorbutic, venereal, and small-pox cases, we have daily instances of this fact. Other internal causes, without any very evident pre-existent disease, sometimes destroy persons by gangrenous mischief, who are but little advanced in years.—(*Saviard, Obs.* 16. *Haller, Disput. Chir. t.* 4, *p.* 551.) Certain poisonous, acrid, caustic substances taken inwardly, or introduced under the skin, may have the same effect, by annihilating the vital action, or destroying the texture of the parts.—(*Lassus, Pathologie Chir. t.* 1, *p.* 31.) But though these observations may all be entirely correct, they by no means justify the conclusion, that the internal causes of mortification ever act like a deleterious matter producing a putrefaction of the fluids. The mortification of the toes and

feet, so well described by Mr. Pott, is supposed to proceed chiefly from unknown internal causes, though sometimes attended with an ossified state of the arteries.

Another remarkable specimen of mortification from an internal cause, is that originating from eating bread made of bad black wheat or rye. Besides occurring as an original idiopathic disease, and from obstruction of arteries, chronic or dry gangrene (observes Dr. Thomson) may be induced by the action of substances taken into the stomach, which seem to produce it as a specific effect in parts remote from the source of the circulation. The most singular example which we have of this is in the gangrene produced by the eating of a particular kind of unsound or diseased rye. This species of mortification has been rarely observed in England; but it has been frequently seen on the continent, where it has been repeatedly known to prevail in some districts, where rye forms a principal article of food, as an endemial disease. It occurs, however, in such districts only after wet seasons, in which that grain is affected with a particular disease, well known in France by the name of the *Ergot*, or cockspur rye. In this disease, the grains of rye grow to a large size, acquire a black colour, and have a compact horny consistence. The species of mortification produced by eating this substance, was first particularly described by Dodard.—(See *Journ. des Savans*, *an.* 1676.) The part affected became at first insensible and cold, and in the progress of the disorder, dry, hard, and withered. In very malignant cases, there was delirium. Dodard's description of the complaint was very imperfect; but he has mentioned a circumstance tending strongly to prove that the disease actually arose from the alleged cause; viz. that fowls fed with cockspur rye are killed by it. Saviard informs us, that he saw this disease in the year 1694, at the Hôtel-Dieu of Orleans. It attacked the upper and lower extremities, which were rendered, in the course of the disorder, as dry as touchwood, and as emaciated as the limbs of Egyptian mummies. In 1710, Noel, surgeon to the Hôtel-Dieu at Orleans, transmitted to the Royal Academy of Sciences at Paris an account of this peculiar mortification. About fifty people, men and children, had come that season into his hospital with the affliction. According to Noel, the disorder always began in the toes, and extended itself gradually along the foot and leg, till it sometimes rose to the upper part of the thigh. He had never seen any of the female sex affected with it, and had observed only one instance of it in the upper extremities. The Academy received the history of one case in which the lower extremities were separated from the body in the articulations of the thighbones with the acetabula; the first example (Dr. Thomson believes) of this separation upon record; and it was the occurrence of this, and of similar cases, that probably first suggested the operation of amputation at the hip-joint.—(See *Thomson's Lectures on Inflammation*, *p.* 541.) As Noel's patients did not come under his care till after the disease had existed some time, he could not describe from his own observation the early symptoms; but the patients had often told him, that the disease generally began in one or both feet, with pain, redness, and a sensation of heat, as burning as the fire; and that, at the end of some days, these symptoms ceased as quickly as they had come on, when the extreme sensation of heat, which they had formerly felt, was changed into cold. The part affected (adds Noel) was black, like a piece of charcoal, and as dry as if it had passed through the fire. After some time, a line of separation was formed between the dead and living parts, like that which appears in the separation of a slough produced by the cautery; and the complete separation of the limb was, in many cases, effected by nature alone. In others, Noel was obliged to have recourse to amputation.

This disease appeared in Switzerland in 1709 and 1716, and its symptoms and progress in that country have been accurately described by Langius in a dissertation entitled "*Descriptio Morborum ex Esu Ciavorum Secalinorum.*"

Gassaud, physician in Dauphiny, where this disease appeared also in 1709, states, that many of the patients were affected with swellings of the feet and legs, and of the hands and arms, which degenerated into a gangrene that penetrated to the bone, and produced a separation of the affected limb. The disorder was attended with different symptoms in different individuals. Some suffered very violent pain, accompanied by an insufferable sensation of heat, although the part affected often felt cold to the touch. In other patients, redness, with much swelling, supervened, attended with fever and delirium. Other patients were without any fever or delirium, though they seemed to suffer equal pain. In some patients, the parts affected became withered, dry, and black, like charcoal. The separation of the dead parts from the living took place with the most excruciating pain, and a sensation resembling that produced by the direct application of fire. This sensation was sometimes intermittent, and in other instances it was succeeded by an equally harassing sensation of cold.

According to Bassau, surgeon to the hospital of St. Antoine in Dauphiny, the cases which he saw were not all of the dry kind; the limb sometimes becoming putrid, and maggots being generated. He says that the disease was not infectious, and it attacked indiscriminately men, women, and children.

The degree of fatality caused by this species of mortification, seems to have been extremely various. In the *Memoirs of the Royal Academy of Sciences* for 1748, M. Duhamel mentions, that of 120 persons afflicted, scarcely four or five recovered with their lives According to Langius, it was equally fatal in Switzerland.

Dr. Thomson believes that the preceding sort of gangrene has never occurred in this country, excepting, perhaps, the cases recorded by Dr. Charlton Woolaston, in the *Phil. Trans.* for 1762; and which proceeded from eating unsound wheat, not rye.—(See *Lectures on Inflammation*, *p.* 548.) For farther particulars relating to this curious kind mortification, I must refer the reader to this valuable work.

The external causes of mortification which are manifest, and act mechanically or chemically, are burns; excessive cold; the application of caustics; the presence of any ichorous, urinary, or fecal matter effused in the cellular substance; violent contusions, such as are produced by gun-shot wounds, or bad fractures; the strangulation of a part, as in cases of hernia, or when polypi or other tumours are tied; a high degree of inflammation; and, lastly, every thing that has the power of stopping the circulation and nervous energy in parts.—(*Lassus*, *Pathologie Chir. t.* 1, *p.* 34, 35.)

Inflammation is one of the most frequent occasional causes of mortification. But, as I have already remarked, the death of a part may take place without any well marked appearance of previous inflammatory disorder; and the latter, even when present, has frequently less share in the mischief than other incidental circumstances, and is, in reality, only an effect of the very same cause which produces the sphacelus itself. It is often a matter of doubt whether actual inflammation precedes the occurrence or not; for a part, before it mortifies, is in certain instances only affected with pain, and with no degree of preternatural redness. Lastly, when mortification is unquestionably preceded by inflammation, there are so many varieties of the disorder depending on incidental causes, that these latter demand more attention than the inflammation.—(*Richter*, *Anfangsgr. b.* 1, *kap.* 3.)

Mr. James enumerates the following circumstances, as capable of influencing, in a very great degree, the disposition of inflammation to terminate in mortification. 1. The powers of the part in which the inflammation occurs, being naturally weak, as in fibrous membranes, the scrotum, &c. 2. The remote supply of blood or nervous energy, as in the lower extremities. 3. Obstruction to the return of blood. 4. To the supply of blood. 5. Disease in the heart or vessels. 6. Debility from age, habits of life, disorder of the digestive organs, or fever. 7. Poor living, foul air, improper food, scurvy, &c. 8. Impairment of organization from external injury. 9. Of the nervous power by poisons. 10. Undue excitement of weakened parts. 11. Depressing remedies. 12. Pressure and tension. 13. Excessive violence of inflammatory action. 14. Peculiar disposition in the constitution.—(*James on Inflammation*, *p.* 102.)

Healthy phlegmonous inflammation seldom ends in mortification, except when it is unusually violent and extensive.

Of all the inflammatory complaints to which the system is liable, phlegmonous erysipelas is observed most frequently to terminate in gangrene. It is a case that demands the prompt employment of active anti-

phlogistic means, and early free incisions when the cellular membrane and fasciæ slough, and a combination of suppuration and mortification is beginning under the skin.

The symptoms of mortification from inflammation take place variously, yet generally as follows:—The pain and sympathetic fever suddenly diminish, the part affected becomes soft, and of a livid colour, losing, at the same time, more or less of its natural warmth and sensibility. In some places, the cuticle is detached; while in other situations vesicles arise, filled with a clear or turbid fluid. Such is the state to which we apply the term *gangrene*, and which stage of the disorder too often rapidly advances to *sphacelus*, when the part becomes a cold, black, fibrous, senseless substance, called in technical language a *slough*.

It merits notice, however, that "in cases in which gangrene immediately succeeds inflammation, these two morbid states may, in some measure, be regarded as stages or periods of the same disease. They pass insensibly into one another; nor is it possible to say precisely where the one state ends, and the other commences. The symptoms of inflammation in these cases do not disappear before those of gangrene come on; but seem rather to undergo a gradual and almost imperceptible change, or conversion, into one another. *The redness acquires a deeper tinge, and spreads farther* than formerly; *the swelling increases and becomes more doughy*; and in this incipient stage, the gangrene, particularly when it attacks the cutaneous texture, often bears a considerable resemblance to erysipelas."—(See *Thomson's Lectures on Inflammation*, *p.* 506.)

It is to be observed, also, that "the part of the body which becomes affected with gangrene *does not immediately lose its sensibility*, for the pain, on the contrary, is often very much aggravated by the approach of this state. *The blood also still continues to circulate*, at least *in the larger vessels of the part*, but perhaps *with less force;* and from the resistance which it meets with in passing through the capillaries, *in less quantity* than formerly. The serous effusion into the cellular membrane continuing to increase, and the action of the absorbent and sanguiferous vessels to diminish, the part becomes at length incapable of being restored to its former office in the animal economy. It is, therefore, in its earlier stages only, that gangrene is to be considered as an affection admitting of cure; for there are limits, beyond which, if it pass, recovery becomes impossible. These limits it may not, in every instance, be easy to define; but they form the boundaries between incipient gangrene and the ultimate termination of that state in sphacelus."—(*Thomson*, *op. cit. p.* 507.)

The causes which produce mortification by impeding the return of blood from the part affected, for the most part operate by making pressure on the trunk or principal branches of a vein. In these instances, there is always an accumulation of blood in the part which first swells, becomes of a livid colour, tense, and very painful. Soon afterward blisters arise, and the part becomes soft, œdematous, cold, insensible, emphysematous, black, and fetid. Such are the circumstances which happen in strangulated hernia, in tied polypi, and in a limb in which the veins have been so compressed by any hard swelling, such as the head of a dislocated bone, as to excite mortification.

Other causes operate by preventing the entrance of arterial blood. The application of a ligature to an artery, as practised in several surgical cases, and all external pressure, that closes the artery or arteries on which a part entirely depends for its supply of blood, have this effect. Mortification does not, however, always take place when the trunk of an artery is rendered impervious, because nature furnishes the necessary supply of blood, through collateral ramifications. But when the disorder does happen, the part commonly first becomes pale, flaccid, and cold, and soon afterward shrinks, loses its sensibility, grows black, and perishes.

In some cases, the mortification proceeds not simply from the interruption of the course of the blood through the principal artery or arteries, but its occurrence is promoted by great violence done to the limb, and in particular by the injection and distention of the cellular membrane with effused blood. No doubt all these causes operated in the fatal example of mortification which followed a fracture of the thigh, attended with laceration of the femoral artery, as related by Sir A. Cooper.—(See *Lancet*, *vol.* 1, *p.* 296.)

It is usually represented by writers, that mortification may proceed from a mere lessening of the communication of blood and nervous energy to a part. However, it is to be observed, that parts deprived of all connexion with the sensorium, by the division or paralytic state of their nerves, do not frequently perish on this account. But as their functions are carried on with less vigour, and their vitality is weakened, the same causes which sometimes produce mortification in parts differently circumstanced, must much more readily occasion it in them. Among the causes of the present species of mortification may be mentioned, great debility, extreme old age, a thickening and ossification of the coats of the arteries, and a consequent diminution of their capacity, and of their muscular and elastic power.

Cowper, the anatomist, was one of the earliest writers who took notice of this ossification of the arteries of the leg, in persons who had died of mortification of the feet and toes.—(See *Phil. Trans. vol.* 23, *p.* 1195, *and vol.* 24, *p.* 1970.) A similar case was remarked by Mr. Becket, of which he has given an account in his *Chirurgical Observations*. The occurrence was also mentioned by Naish.—(See *Phil. Trans. vol.* 31, *p.* 226.) Dr. J. Thomson has seen one example of a very complete ossification of the arteries of the leg, accompanying a mortification of the feet and toes. —(*On Inflammation*, *p.* 537.) Speaking of the same subject, Mr. Hodgson remarks: "Experience has proved this condition of the arteries to be at least a constant attendant upon one species of gangrene, to which the extremities of old subjects are liable; and I have found the three principal arteries of the leg nearly obliterated by calcareous matter in two fatal cases of this disease. But our knowledge of the power of collateral circulation, in every part of the body, will not allow us to admit the obliteration of the trunks as a sufficient cause of mortification, from a deficient supply of blood. It is therefore necessary for us to remember, that the same disease may probably exist in the collateral branches, upon which it has produced similar effects. But if an extent of vessel be converted into a calcareous cylinder, it loses its elasticity and organic powers, so as to be unable to afford any assistance to the propulsion of the blood; and the existence of parts, supplied by vessels in this state, constitutes a strong argument against the agency of the arteries in the circulation of the blood. The above observations, on the cause of this species of gangrene, at once expose its incurable nature; and this state of the blood-vessels renders the danger of amputation very considerable, unless fortunately the disease in the arteries does not extend to the part at which the ligature is applied."—(See *Hodgson on Diseases of the Arteries and Veins*, *p.* 41.) However, although the ossified state of an artery must certainly be unfavourable to its healing, it does not constantly prevent this desirable event.—(See *Case in Medico-Chir. Trans. vol.* 6, *p.* 193.)

The preceding facts are particularly entitled to attention, because, as we shall presently find, the opinion that the mortification of the toes and feet arose from an ossification of the arteries was considered by Mr. Pott as destitute of foundation.

It is probable, however, that sometimes other causes are concerned. Fabricius Hildanus mentions a fatal case of mortification of the feet and legs, where the patient was in the vigour of life, and apparently of good constitution. After death, a scirrhous tumour was found surrounding and compressing the inferior vena cava and aorta, near their bifurcation, so as to prevent the free circulation of the blood in the lower extremities. Mortification of the extremities also sometimes occurs from deficient circulation in the progress of diseases of the heart. In a case of dropsy of the chest, Sir A. Cooper has seen a small spot on the leg become all at once black, without any appearance of inflammation.—(See *Lancet*, *vol.* 1, *p.* 296.)

The mortification arising from long continuance in the same posture, is chiefly attributable to debility and the unremitted pressure which parts sustain, and which obstructs the circulation. Surgeons have frequent occasion to see melancholy examples of this kind of mortification, particularly in cases of fractures, paralysis from disease of the vertebræ, injuries of the

spine or pelvis, &c. The mischief most readily occurs where the bones have the least flesh upon them, and, consequently, where all external pressure has the greatest effect; as, for instance, about the os sacrum, os ileum, spines of the scapulæ, &c. The disordered part always first becomes soft, livid, red at the circumference, and œdematous, afterward losing its sensibility, and acquiring a black appearance; at length it is converted into a foul sloughing ulcer.

Though long continuance in the same posture is the grand cause of this kind of mortification, yet incidental circumstances are frequently combined with it, and have great influence over the disorder. These are, great debility, the same state of the system, as exists in typhus fever, impure air, unclean bedding, &c. According to Sir A. Cooper, some fevers have a greater tendency than others to produce gangrene, as is the case with scarlatina. In slight cases of this disorder, he says, the most horrible effects will sometimes arise from gangrene. The tonsils will slough to a great extent; parts of the Eustachian tube, and even the tympanum will separate, and large portions of bone exfoliate. He also adverts to the dangerous sloughing frequently brought on in the measles by the application of large blisters to the chests of children, and points out the disposition to sloughing, occasioned by the immoderate use of mercury, or by whatever tends to weaken the constitution.—(See *Lancet, vol.* 1, *p.* 295.)

There are some causes which produce death in a part at once, by the violence of their operation. A very powerful blow on any portion of the body may destroy its vitality in this sudden manner. Lightning, strong concentrated acids, and gun-shot violence sometimes act in a similar way. When a ball enters parts with great force and rapidity, many of the fibres which are in its track are frequently killed at once, and must be thrown off in the form of sloughs, before the wound can granulate and heal.—(See *Hunter on Gun-shot Wounds.*)

Cold is often another cause of mortification, and, when parts which have been frozen or frost-bitten are suddenly warmed, they are particularly apt to slough.

I find in Baron Larrey's valuable publication some interesting observations on the gangrene from cold. He acquaints us, that after the battle of Eylau, one of the most grievous events to which the French soldiers were exposed, was the freezing of their feet, toes, noses, and ears: few of the vanguard escaped the affliction. In some, the mortification was confined to the surface of the integuments of the toes or heels; in some, the skin mortified more deeply, and to a greater or less extent; while in others, the whole of the toes or foot was destroyed.—(See *Programma quo frigoris acrioris in corpore humano effectus expendit. Haller, Disp. ad Morb. Lips.* 1775.)

"All the writers on this species of mortification (says Larrey) have considered cold as the determining cause; but if we attend to the period when the complaint begins, and the phenomena which accompany it, we shall be convinced that cold is merely the predisposing cause. In fact, during the three or four exceedingly cold days which preceded the battle of Eylau (the mercury having then fallen to 10, 11, 12, 13, 14, and 15 degrees below zero of Reaumur's thermometer), and until the second day after the battle, not a soldier complained of any symptom depending upon the freezing of parts. Nevertheless, they had passed these days, and a great portion of the nights of the 5th, 6th, 7th, 8th, and 9th of February in the snow and the most severe frost. The imperial guard especially had remained upon watch in the snow, hardly moving at all for more than four-and-twenty hours, yet no soldier presented himself at the ambulance,* nor did any one complain of his feet being frozen. In the night of the 9th and 10th of February the temperature suddenly rose, the mercury ascending to 3, 4, and 5 degrees above zero. A great quantity of sleet, that fell on the morning of the 10th, was the forerunner of the thaw, which took place in the course of that day, and continued in the same degree for several days. From this moment, many soldiers of the guards and the line applied for succour, complaining of acute pain in the feet, and of numbness, heaviness, and prickings in the extremities. The parts were scarcely swollen, and of an obscure red colour. In some cases a slight redness was perceptible about the roots of the toes and on the back of the foot. In others, the toes were destitute of motion, sensibility, and warmth, being already black, and, as it were, dried. All the patients assured me that they had not experienced any painful sensation during the severe cold, to which they had been exposed on the night watches of the 5th, 6th, 7th, 8th, and 9th of February, and that it was not till the night of the 10th, when the temperature had risen from 18 to 20 degrees, that they felt the first effects of the cold." It is farther noticed by Larrey, that such patients as had opportunities of warming themselves in the town, or at the fires of the night watches, suffered in the greatest degree.—(See *Mémoires de Chirurgie Militaire, t.* 3, *p.* 60—62.)

Sometimes mortification seems to depend either upon the operation of some infectious principle, or, at all events, upon causes which simultaneously affect numerous individuals; for instances have been known, in which almost all the ulcers and wounds in large hospitals became nearly at the same time affected with gangrenous mischief.—(See *Hospital Gangrene.*)

Mortification is very frequently occasioned by the injury which parts sustain from the application of fire and heated substances to them. When the heat is very great, the substance of the body is even decomposed, and of course killed at once. On other occasions, when the heat has not been so violent, nor sufficiently long applied, inflammatory symptoms precede the sloughing.

Cutaneous texture is that in which we have the best opportunity of observing the phenomena and progress of gangrene. When it occurs as a consequence of inflammation, the colour of the skin changes from the florid red to a darker shade; and in the progress of the disease it acquires a livid hue. The cuticle often separates at certain points from the skin, and the vesications, termed *phlyctenæ*, are formed, which usually contain a bloody-coloured serum. As sphacelus comes on, the livid hue disappears, and a slough is formed, which is sometimes ash-coloured; sometimes black. It is not always easy to judge of the extent of mortification from the appearance of the skin; for when the subjacent cellular membrane is affected, the disorder may occupy a greater extent internally than upon the surface.

In a spreading gangrene, the red colour of the affected skin is insensibly lost in the surrounding integuments; but when gangrene, followed by sphacelus, stops, a red line, of a colour more lively than that of gangrene, is generally perceptible between the dead and living parts. It is at the inner edge of this inflamed line where we usually see the ulcerating process begin, by which the separation of the dead from the living parts is effected.—(See *Thomson's Lectures on Inflammation, p.* 511, 512.)

Mortification frequently takes place in cellular texture. The skin which covers dead cellular substance generally has a gangrenous appearance, and afterward either ulcerates or sloughs. In some cases, the portion of sphacelated cellular texture is small, as in the malignant boil; in others, extensive, as in cases of carbuncle. In erysipelas phlegmonoides, the cellular membrane, connecting together the muscles, tendons, nerves, blood-vessels, &c. often perishes to a great extent. Here large portions of skin are frequently also destroyed by sloughing or ulceration, so that muscle, blood vessel, tendon, nerve, &c. are exposed to view, quite denuded of their proper coverings, and in different states of disease.

Artery is the texture endowed with the greatest power of resisting its own destruction by mortification. "I have (says Dr. Thomson) in various instances of erysipelas phlegmonoides, seen several inches of the femoral artery laid completely bare by the gangrene, ulceration, and sphacelus of the parts covering it, without its giving way before death. The arteries in these, and other similar instances, in which I have seen them laid bare in the neck and arm, by abscess terminating in mortification, had the appearance of raw flesh, and were obviously thicker and more vas-

* The ambulances of the French army are caravans, furnished with an adequate number of surgeons, and every requisite for the dressing of wounds, and the immediate performance of operations, upon which last circumstance, in particular, the life of the wounded soldier often depends. They follow the most rapid movements of the army, and are capable of keeping up with the vanguard.

cular than natural. The blood circulated through them, and assisted in supplying with nourishment the parts upon which they were distributed."—(*P.* 523.) I have often seen the truth of the foregoing statement sadly illustrated in cases of sloughing buboes, by which several inches of the femoral artery were exposed. I have seen the throbbing brachial artery denuded for more than a month, nearly its whole extent along the inside of the arm, by the ravages of malignant and pseudo-syphilitic ulceration, attended with repeated sloughing; and yet hemorrhage had no share in carrying off the unfortunate patient.

It is a curious fact, that the blood coagulates in the large arteries which lead to a mortified part. This occurrence takes place for some distance from the slough, and is the reason why the separation of a mortified limb is seldom followed by hemorrhage.

The same occurrence also affords an explanation why, in the amputation of a mortified limb, there is sometimes no hemorrhage from the vessels, although the incisions are made in the living part. This fact was first particularly pointed out by Petit, the surgeon. —(See *Mém. de l'Acad. des Sciences*, 1732.) "When a gangrened limb (says this celebrated surgeon) is cut off in the dead part, no hemorrhage occurs, because the blood is coagulated a great way in the vessels." He adds, "We have several examples of limbs amputated, on account of gangrene, in which no hemorrhage occurred, although the amputation was made a considerable way in the living parts; because the clot was not confined in these cases to the dead part, but was continued forwards into the living, as far as the inflammatory disposition extended."

According to Dr. Thomson, cases in confirmation of the foregoing statement are recorded by other practical writers, especially Quesnay, and Mr. O'Halloran. In one of the cases mentioned by the latter gentleman, and in which no hemorrhage followed the removal of the limb, the incisions were made four inches above the division of the dead from the living parts. Dr. Thomson has seen a still longer portion of femoral artery closed up with coagulated blood, after a mortification of the foot and leg; and, in one example, where the mortification began in the thigh, he saw the coagulation of the blood in the external iliac, extending up to the origin of this vessel from the aorta. "So common, indeed, is this coagulation of the blood in the limbs affected with mortification (observes Dr. Thomson), that it has been supposed to be a necessary and constant effect of this disease. This opinion, however, does not appear to be well founded; for I have now seen several instances in which a limb has mortified and dropped off, without hemorrhage having occurred from the vessels divided by nature: and yet, in examining the vessels of the stumps of these patients after death, I have not been able to find any clots, either of coagulated blood, or of coagulable lymph. In the cases to which I allude, the adhesive inflammation occuring in the line of separation between the dead and living parts, had extended to the blood-vessels, and their inner surfaces, being inflamed and pressed together by the swelling which occurs, had adhered so as to close up their extremities. It is in this way we shall find that the common ligature acts, which is applied to the divided extremities of arteries and veins; and it is this obliteration by the process of adhesion of the extremities of the arteries and veins in the neighbourhood of the sphacelated parts, that in reality prevents the occurrence of hemorrhage when the mortified limbs fall off, or are removed by the knife. The coagulation of the blood in the canal of the vessel is not alone sufficient. It may tend, in the cases in which it occurs, for a time, to restrain hemorrhage; but it is by the obliteration by adhesion of the canal in the extremities of the arteries and veins that the occurrence of hemorrhage can be securely and permanently provided against. Indeed, to me, it seems doubtful, whether the coagulation of the blood, which takes place in mortified limbs, ever takes place in the canal of the vessel, till its extremity and lateral communications have been plugged up by the coagulating lymph, which is extended during the state of the adhesive inflammation."—(*See Thomson's Lectures on Inflammation*, *p.* 554.)

If gangrene and sphacelus happen to any extent, the patient is usually troubled with an oppressive hiccough; a symptom well known to the surgeon of experience, and often an indication of the mischief, when external signs are less instructive. The truth of this remark is frequently seen in strangulated hernia.

The constitution also suffers immediately a considerable dejection. The patient's countenance suddenly assumes a wild cadaverous look; the pulse becomes small, rapid, and sometimes irregular; cold perspirations come on, and the patient is often affected with vomiting, diarrhœa, and delirium.

As Dr. Thomson observes, the constitutional symptoms "form fevers, which partake in individual cases, more or less, of an inflammatory, typhoid, or bilious character. But the degree of these fevers varies in every particular case, from their almost total absence to the highest degree of intensity. The skin is usually hot and dry at the commencement of the attack; the tongue is without moisture, brown and hard; the pulse is quicker, and less full and strong, than in inflammation; and this state of the pulse is often attended by flattering intermissions, and a considerable degree of subsultus tendinum. The fever has, in general, more of the asthenic than of the sthenic character; or it is more of the typhoid than of the inflammatory type; a circumstance of great importance in the constitutional treatment of mortification. The fever in gangrenous affections is often accompanied with great uneasiness and restlessness, dejection of spirits, wildness of the looks; and, in severe cases, with almost always more or less delirium. In the progress of the disease, cold sweats, palpitations, and convulsions sometimes occur; a hiccough, accompanied with nausea, often comes on, and proves a most distressing symptom to the patient. Frequently this hiccough is the forerunner of death. Some patients die comatose; others, after suffering severe pains, spasms, and delirium. But in some, a slow, in others, a sudden abatement of the constitutional symptoms takes place, accompanied also with the amelioration of the local affection. The gangrenous inflammation stops, and a red line is formed by the adhesive inflammation in the extreme verge of the living parts; the dead part separates, and granulations form; and when the constitution has strength to sustain the injury it has received, recovery takes place."—(See *Lectures on Inflammation*, *p.* 509.)

It is an erroneous supposition, that mortification, arising from an external local cause, is more easily stopped and cured than that originating from an internal cause. The local cause is sometimes extremely difficult, or even incapable of removal; and a sphacelus, which is at first entirely local, may afterward become a general disorder, by the universal debility and derangement of the system, resulting from the complaint. Hence, it is obvious, that a sphacelus may easily extend beyond the bounds of its outward local cause. On the other hand, a mortification may be reduced to one of a nature entirely local; though it arose at first from constitutional causes. Sphacelus from extreme debility, or from such a state of the system as attends the scurvy, typhoid fevers, &c., is constantly perilous, because these causes are very difficult to remove. It is also a fact, that when numerous causes are combined, it is an unfavourable occurrence, not merely because the surgeon is apt to overlook some of them, but because there are in reality more obstacles to the cure.

Humid gangrenes, which are frequently accompanied with emphysema of the cellular membrane, usually spread with great rapidity.—(See *James on Inflammation*, *p.* 96.)

Sometimes a mortification spreads so slowly, that it does not occupy much extent at the end of several months, or even a whole year. The case, however, is often not the less fatal on this account. The danger is never altogether over, until the dead part has completely separated. The entrance of putrid matter into the circulation (says Richter) is so injurious, that patients sometimes perish from this cause, long after the mortification has ceased to spread.—(*Anfangsgr. der Wundarzn. b.* 1, *kap.* 3, *p.* 78, 79.)

This last circumstance is very much insisted upon by all the modern continental surgeons; but the doctrine has never gained ground among English surgeons, who entertain little apprehension of the bad effects of the absorption of putrid matter in cases of mortification; and the opinion of Mr. Guthrie may be more correct, that nature receives the shock through the nervous system, and not through the absorbents.—(*On Gun-shot Wounds*, *p.* 123, *ed.* 2.)

The idea of a deleterious principle being absorbed was long ago well refuted by Mr. J. Burns, who pointed out, that the impression upon the constitution was in no degree commensurate with the size of the slough, and consequently with the quantity of putrid matter, as the effects produced by a small slough of intestine, or cornea, will exemplify. But when the sloughs are of equal size, and in the same parts, the differences of constitutional sympathy, as Mr. James observes, may depend upon the nature of the surrounding inflammation, which, however, he conceives, may itself be affected by the quantity of putrid irritating fluids.—(*On Inflammation*, *p.* 98.)

The danger of sphacelus materially depends upon the size and importance of the part affected, and upon the patient's age and constitution. The indications already specified of the stoppage of mortification, must also considerably influence the prognosis, especially the red line at the edge of the living parts, and the incipient separation of the dead from the living parts.

Sphacelus implies the total loss of life in the part affected, the destruction of its organization, the abolition of all its functions, and an absolute inability to resume them again. However, even when we see the surface of a part manifestly sphacelated, we must not always conclude that the entire destruction of its whole substance or thickness is certain; for, in many cases, the disorder only affects the skin and cellular substance. In this state, the integuments frequently slough away, leaving the tendons, muscles, and other organs perfectly sound.

TREATMENT OF MORTIFICATION.

I shall arrange under two heads what is to be said of the treatment of mortification. Under the first will be comprehended every thing which relates to internal remedies, and such other means as are indicated by the general state of the system; under the second, topical remedies, and the local treatment of the parts affected.

In the treatment, the surgeon will always have one thing for immediate consideration; viz. whether the case before him is one of acute mortification, attended with inflammation and inflammatory fever; or whether it is a chronic mortification, beginning without fever, or attended with a fever of a typhoid nature and great prostration of strength? By making up his mind upon this point, the practitioner will establish a useful general principle for his guidance, especially in the commencement of the treatment.

1. When mortification is acute, and seems to depend on the violence of inflammation, the first indication is to moderate the inordinate action of the sanguiferous system, by the prudent employment of such means as are proper for counteracting inflammation. In short, relief is to be sought in the antiphlogistic regimen, which consists in the employment of blood letting, purgatives, diaphoretics, and diluents, and in abstinence from all vegetable or animal substances, which have a tendency to excite, or to augment the febrile action. This regimen must be pursued as long as inflammatory fever continues. It is only in cases in which the fever from the first assumes a typhoid character, or where the mortification takes place without the previous occurrence of fever, that any deviation from the antiphlogistic regimen can be allowed.

Dr. Thomson, from whom I have borrowed the foregoing passage, also notices the present common aversion to bleeding in compound fractures, erysipelas, carbuncles, hospital gangrene, burns, and frost-bite; cases in which the patient, it is said, can seldom bear with impunity any considerable loss of blood. "In many instances of these injuries and affections (says he) blood-letting, I know, is not required; but I am doubtful, even if it were generally employed, whether it would produce all the mischiefs which have of late years been ascribed to it. I believe it to be the most efficacious of any of the remedies that can be employed in all cases of inflammatory fever threatening to terminate in gangrene, and that its use in such cases ought never to be omitted in the young, strong, and plethoric."—(See *Lectures on Inflammation*, *p.* 559.) When bleeding has not been sufficiently practised, during the inflammation antecedent to mortification; when the general symptoms, which point out the existence of this state, continue violent; and especially when the pulse is still quick, hard, or full; it is absolutely necessary to empty the vessels a little more, even though mortification may have begun, particularly if the patient be young and plethoric. Bleeding, by diminishing the fever, and abating the general heat, is frequently the best means of all. It may then be considered better than all antiseptics for stopping the progress of the disorder. But this evacuation is to be employed with a great deal of circumspection; for, should it be injudiciously resorted to, from the true state of the system not being understood, the error may be followed by the most fatal consequences. Owing to the constitution being generally broken by intemperance, or enfeebled by an impure atmosphere, Sir A. Cooper considers it rarely safe in this metropolis to take blood from the arm, with a view of checking gangrene; though he acknowledges that the removal of a few ounces of blood is a practice which sometimes answers in the country. It should also be well remembered, that however strongly bleeding may be indicated, the moment is not far off when this evacuation is totally inadmissible, especially if the mortification make much progress.

In cases of acute mortification, after as much blood has been taken away as may be deemed safe or proper, the other parts of the antiphlogistic regimen must be continued as long as any increased action of the heart and arteries continues. "The use of purgatives seems to be particularly required in those cases in which the local inflammatory affection is accompanied with derangement of the digestive and biliary organs. Antimonial diaphoretics are those from which I should be inclined to expect most advantage in the commencement of the attack; but after the inflammatory action has been subdued, opiates, either alone or combined with antimony, or, what is still better, with ipecacuanha, as in Dover's powder, are frequently of singular service, not only by diminishing pain, but also by inducing a soft and moist state of the skin."—(*Thomson*, *p.* 560.) A strict regimen, which may have been useful and even necessary during the inflammatory stage, may have a very bad effect if continued too long, by diminishing the patient's strength, which, on the contrary, should be supported by the most nourishing food.

Sir A. Cooper recommends two or three grains of the submuriate of mercury at night, in order to restore the secretions of the intestinal canal and liver; and the liquor ammoniæ acetatis, with a few drops of the tinct. opii, several times a day, with the view of lessening irritability, and tranquillizing the system.

A vegetable diet, as Dr. Thomson observes, is to be preferred in the commencement both of acute gangrene with inflammatory fever, and of chronic gangrene with a fever from the first of a typhoid nature. Wine and animal food given too early in diseases which have a tendency to gangrene increase the febrile heat and frequency of the pulse, oppress the stomach, render the tongue foul, the patient restless and delirious, and his situation dangerous, if not hopeless. In the transition from gangrene to sphacelus an abatement of the symptomatic fever usually takes place in almost all cases which have ultimately a favourable termination. Dr. Thomson believes that *this is the first period at which it is safe to allow vinous liquors, or diet chiefly animal.*—(*P.* 561.)

I next come to a second very essential and important indication to be fulfilled as soon as the symptoms, announcing the existence of the inflammatory state, appear to abate, and the patient begins to be debilitated. This indication is *to prevent excessive weakness by the suitable employment of cordials, and particularly of tonics.* These same means also contribute to place the system in a proper state for freeing itself from the mortified parts, or in other words for detaching them. For inflammation is the preparatory step which nature takes to accomplish the separation of mortified parts from the living ones, and this salutary inflammation cannot take place if the energies of life be too much depressed.

In order to fulfil the above indication, it is necessary to prescribe a nourishing diet, with a certain quantity of good wine, proportioned to the patient's strength and the symptoms of the complaint. This diet is generally productive of more real benefit than the whole class of cordial and stimulating medicines. However, when the patient is much weakened, when the mortification of the part affected is complete, and the disorder is spreading to others, some of the follow

ing remedies may be ordered: ammonia, aromatic confection, ether, &c. In general, however, wine is better, because more agreeable than cordials; and for this purpose we ought to prefer the most perfect wines, such as those of Spain and Madeira.

Of all the medicines hitherto recommended for the stoppage of mortification, none ever acquired such a character for efficacy as the Peruvian bark. It is said that this remedy often stops in a very evident and expeditious manner the course of the disorder. Being a very powerful tonic, it is thought to operate by strengthening the system, and thus maintaining in every part the necessary tone for resisting the progress of mortification. But whatever may be its mode of acting, the advocates for this medicine contend that it ought to be employed in almost all cases of mortification, as soon as the violence of the inflammatory symptoms has been appeased.

It was Mr. Rushworth, a surgeon at Northampton, who made this discovery in the year 1715. Amyand and Douglas, two surgeons in London, soon afterward confirmed the virtue of this remedy. Mr. Shipton, another English surgeon, also described, in the Philosophical Transactions, the good effects which he saw produced by it. In the Medical Essays of Edinburgh, Drs. Monro and Paisley published several case illustrative of its efficacy. We are there informed, that when its exhibition was interrupted, the separation of the eschars was retarded, and that on the medicine being resorted to again, the separation went on again more quickly. Since this period, all practitioners in England and elsewhere have employed bark very freely in the treatment of mortification; and the exaggerated statements of its effects led to its exhibition in all cases of this nature without discrimination of the varying states of the general health and local disorder in the different stages of the complaint, and without any reference to its causes and nature, which are subject to variety.

We cannot indeed doubt that bark has frequently had the most salutary effect in cases of mortification, though sometimes it may probably have had imputed to it effects which were entirely produced by nature. The following observation made by Dr. Thomson is highly worthy of recollection: "In attending to the effects supposed to result from the operation of the external and internal remedies which are daily employed for the cure of mortification, there are two facts, well ascertained, which appear to me to be peculiarly deserving of your regard. The first of these is, that mortification often stops spontaneously, without any assistance whatever from medicine; the second that it often begins and continues to spread, or even after it has stopped for a while recommences, and proceeds to a fatal termination in spite of the best directed efforts of the healing art."—(See *Lectures on Inflammation*, *p.* 557.)

It is quite wrong to prescribe bark in every instance, for there are many cases in which it is unnecessary, some in which it does harm, and others in which it is totally inefficacious. It is a medicine obviously of no service when the mortification arises from an external cause, and is the only complaint in a healthy, strong constitution. It is equally unnecessary when the sphacelus is of the dry sort, and has ceased to spread, at the same time that the living margin appears to be in a state of inflammation without any universal debility. But it deserves particular notice, that the circumstances of each individual case are liable to so considerable a variation, that though bark may be at first unnecessary, it may afterward be indicated.

When mortification is complicated with serious disorder of the functions of the abdominal viscera, a very frequent case, bark is manifestly pernicious. Here, the indication is to correct the state of the stomach and bowels with mild opening medicines, and especially calomel. When this has been done, if bark should be indicated by any of the circumstances already pointed out, it may be safely administered.

Sometimes mortification is accompanied with a low typhoid kind of fever, which, whether the cause or the consequence of the local mischief, may require the exhibition of bark.

However, mortification may be attended with common inflammatory fever, and then the living margin is generally inflamed and painful. This is particularly the case, when mortification is the consequence of genuine acute inflammation, or of an external injury, in a healthy subject. Here bark must obviously be injurious. Still it is wrong to regard this medicine as invariably hurtful whenever sphacelus is the effect of inflammation. It has already been observed, that the inflammation frequently has less share in the origin of the disorder, than some incidental cause, which often requires the exhibition of bark. Even when mortification is the pure effect of inflammation, great prostration of strength may subsequently arise, and indeed does mostly take place at a certain period of the disorder. In this circumstance the voice of experience loudly proclaims the utility of bark, though its exhibition would have been at first useless or hurtful While genuine inflammatory fever and local inflammation are co-existent with mortification, antiphlogistic means are undoubtedly useful; but great caution is requisite, since, in cases of humid gangrene, as it is termed, the inflammatory state very soon changes into one in which the great feature is prostration of strength.

When there is mere prostration of strength without any symptom of gastric disorder, or of inflammation, or typhoid fever, bark is evidently proper, though seldom effectual alone; diaphoretic and nervous medicines being also necessary, opium, wine, camphor, ammonia, brandy, &c.

We meet with one species of mortification in which the patient experiences severe pain in the part, without the smallest appearance of inflammation. Here bark is never of much use, and opium has been represented as the medicine in which we should principally confide. This subject will be more fully considered presently, when Mr. Pott's remarks on a peculiar mortification of the toes and feet will be introduced.

Bark sometimes occasions purging, and then it must be immediately discontinued, unless that hurtful effect can be prevented by the addition of a few drops of laudanum to each dose, or by employing the sulphate of quinine, instead of the common preparations. Bark frequently disagrees with the stomach; in which case, I should say, that it ought not to be continued at all; though, in this circumstance, the usual plan has been to give, instead of the decoction, the infusion or the powder finely divided, and mixed with wine, or some aromatic water. Here the sulphate of quinine is likely to prove the safest preparation of bark; but farther experience with respect to its real efficacy is still needed.

Several years ago I published a critique on the indiscriminate employment of bark in cases of mortification, and my remarks were inserted in the article *Gangrene* in *Dr. Rees's Cyclopædia*. Many of them were introduced into the second edition of this Surgical Dictionary, printed in 1813.—(See *Cinchona*.) Since this period, I am happy to find that the blind enthusiasm with which bark was prescribed is beginning to subside, and that on this subject some eminent surgeons have of late publicly avowed sentiments which entirely coincide with my former statements. "I think (says Dr. Thomson) I have frequently seen it prove hurtful when administered in cases of mortification, by loading the stomach of the patient, creating a dislike to food, and sometimes by exciting an obstinate diarrhœa. *I believe it to be in mortification a medicine completely inert and inefficacious.*"—(See *Lectures on Inflammation*, *p.* 563.) By this expression, Professor Thomson does not mean that bark can never be useful in cases of mortification, but only that it has no specific power in checking the disorder, as many have erroneously inculcated.

"Bark (says Boyer) has been considered, by several distinguished English practitioners, as a true specific against gangrene in general, and especially against that which depends upon an internal cause; but subsequent observations to those published in England have proved, that it has no power over the immediate cause of gangrene, and that it only acts as a powerful tonic in stopping the progress of the disorder, and promoting the separation of the mortified parts."—(See *Maladies Chir. t.* 1, *p.* 151, *Paris*, 1814.) Boyer also particularly objects to bark being given while inflammatory fever prevails; but whenever he prescribes bark in cases of mortification, he seems to entertain the old prejudice of expecting benefit in proportion to the quantity which can be got into the stomach. On the contrary, Mr. Guthrie declares that he has not found

bark useful, "farther than as a tonic, and given in such quantities as not to overload the stomach" (*On Gun-shot Wounds*, *p.* 148, *ed.* 2), a plan which I have always recommended. For farther observations on bark, the reader is referred to the article *Cinchona*.

Sulphuric acid may sometimes be advantageously given with bark or quinine; and the citric, muriatic, and nitric acids are occasionally prescribed.

Carbonic acid gas is another remedy of the highest efficacy in chronic mortification. It has even been known to produce highly beneficial effects when bark has been of no service. Water impregnated with it may be recommended as common drink.

Hospital gangrene is a case for which bark has been recommended. The best mode of treating this particular case, however, has been detailed in a separate article.—(See *Hospital Gangrene*.)

A third indication, which should be observed together with the second, or which should even precede it in many instances, is *to lessen the irritability and sufferings of the patient, by the use of opium.* Attention to this desideratum frequently contributes more than any thing else to stop the progress of the disorder, and is often indispensable, in order to promote the operation of other remedies. In all cases of mortification, every thing which heats, irritates, or adds to the patient's sufferings, appears, in general, to augment the disorder and increase the rapidity of its progress. On the other hand, every thing which tends to calm, assuage, and relax, frequently retards the progress of mortification, if it produce no greater good. The pain also, which is a constant mark of too much irritation, contributes of itself to increase such irritation, and in this double point of view, we cannot do better in the majority of cases, than endeavour to appease it by the judicious and liberal use of opium. When the inflammatory stage evidently prevails, this medicine may be conjoined with antiphlogistic remedies, such as the nitrate of potassa, antimony, &c. In other instances, attended with debility, it may be given with bark and cordials.

Mr. Pott describes a species of mortification, for which he sets down bark as ineffectual, and opium the remedy which ought to be chiefly depended upon. The case here alluded to is very unlike the mortification from inflammation, that from external cold, from ligature, or bandage, or from any known and visible cause, and this as well in its attack as in its progress. In some few instances, it makes its appearance with little or no pain; but in the majority of the cases, the patients feel great uneasiness through the whole foot and joint of the ankle, particularly in the night, even before these parts show any mark of distemper, or before there is any other than a small discoloured spot on the end of one of the little toes. It generally makes its first appearance on the inside, or at the extremity of one of the smaller toes, by a small black or bluish spot; from this spot the cuticle is always found to be detached, and the skin under it to be of a dark red colour. If the patient has lately cut his nails, or corn, it is most frequently, though very unjustly, ascribed to such operation. In some patients, it is slow and long in passing from toe to toe, and from thence to the foot and ankle; in others, its progress is rapid and horridly painful: it generally begins on the inside of each small toe before it is visible either on its under or upper part; and when it makes its attack on the foot, the upper part of it first shows its distempered state by tumefaction, change of colour, and sometimes by vesication; but wherever it is, one of the first marks of it is a separation or detachment of the cuticle.

Each sex is liable to it; but (says Mr. Pott), "for one female in whom I have met with it, I think I may say that I have seen it in at least twenty males. I think also that I have much more often found it in the rich and voluptuous than in the labouring poor; more often in great eaters than free drinkers. It frequently happens to persons advanced in life, but it is by no means peculiar to old age. It is not in general preceded or accompanied by apparent distemperature either of the part or of the habit. I do not know any particular kind of constitution which is more liable to it than another; but as far as my observation goes, I think that I have most frequently observed it to attack those who have been subject to flying uncertain pains in their feet, which they have called gouty, and but seldom in those who have been accustomed to have the gout regularly and fairly. It has by some been supposed to arise from an ossification of vessels; but for this opinion I never could find any foundation but mere conjecture."

In this article, I have already stated the observations of Cowper, Dr. Thomson, and Mr. Hodgson, upon the ossified state of the arteries in this species of mortification. The facts recorded by the two latter writers at least prove, that the opinion is founded not upon mere conjecture, as Mr. Pott alleges, but upon actual observation and experience.

In this particular kind of mortification, Mr. Pott found bark, used internally or externally by itself, or joined with other medicines, completely ineffectual.

Mr. Pott afterward relates the first cases in which he gave opium. His plan was generally to give one grain every three or four hours; but never less than three or four grains in the course of four-and-twenty hours. However, he did not propose opium as a universal infallible specific: but only as a medicine, which would cure many cases not to be saved by bark.

The observations of Mr. Pott on the local treatment of these cases are of great practical importance: no part of his writings has a stronger claim to attention.

"I have found (says he) more advantage from frequently soaking the foot and ankle in warm milk, than from any spirituous or aromatic fomentations whatever; that is, I have found the one more capable of alleviating the pain which such patients almost always feel, than the other; which circumstance I regard as a very material one. Pain is always an evil, but in this particular case, I look upon it as being singularly so. Whatever heats, irritates, stimulates, or gives uneasiness, appears to me always to increase the disorder, and to add to the rapidity of its progress; and, on the contrary, I have always found that whatever tended merely to calm, to appease, and to relax, at least retarded the mischief, if it did no more."

Mr. Pott afterward observes: "Cases exactly similar, in all circumstances, are not to be met with every day, but I am from experience convinced, that of two, as nearly similar as may be in point of pain, if the one be treated in the usual manner, with a warm, stimulating cataplasm, and the other only with a poultice made of the fine farina seminis lini, in boiling milk or water, mixed with ung. sambuc. or fresh butter, that the pain and the progress of the distemper will be much greater and quicker in the former than in the latter.

"When the black or mortified spot has fairly made its appearance on one or more of the toes, it is the general practice to scarify or cut into such altered part with the point of a knife or lancet. If this incision be made merely to learn whether the part be mortified or not, it is altogether unnecessary; the detachment of the cuticle, and the colour of the skin, render that a decided point: if it be not made quite through the eschar it can serve no purpose at all; if it be made quite through, as there is no confined fluid to give discharge to, it can only serve to convey such medicines as may be applied for the purpose of procuring digestion to parts capable of feeling their influence, and on this account they are supposed to be beneficial, and therefore right.

"When the upper part of the foot begins to part with its cuticle and to change colour, it is a practice with many to scarify immediately; here, as in the preceding instance, if the scarifications be too superficial, they must be useless; if they be so deep as to cause a slight hemorrhage, and to reach the parts which have not yet lost their sensibility, they must do what indeed they are generally intended to do, that is, give the medicines which shall be applied an opportunity of acting on such parts.

"The medicines most frequently made use of for this purpose are, like the theriaca, chosen for their supposed activity; and consist of the warm pungent oils and balsams, whose action must necessarily be to stimulate and irritate: from these qualities they most frequently excite pain, which, according to my idea of the disease, is diametrically opposite to the proper curative intention: and this I am convinced of from repeated experience.

"The dressings cannot consist of materials which are too soft and lenient; nor are any scarifications necessary for their application. But I would go farther, and say, that scarifications are not only useless, but in my opinion prejudicial, by exciting pain, the great and

chiefly to be dreaded evil in this complaint. The poultice should be also soft, smooth, and unirritating; its intention should be merely to soften and relax; it should comprehend the whole foot, ankle, and part of the leg; and should always be so moist or greasy as not to be likely to become at all dry or hard between one dressing and another."

Sir A. Cooper generally recommends a poultice composed of port wine and oatmeal, or that made with stale beer-grounds; but in one case which I attended with him in private practice, and which will be presently mentioned, a camphorated lotion, fomentations, occasionally a solution of the chloruret of soda, and emollient poultices, were all tried in vain. Indeed, the very nature of the disease leaves little hope of essential good from topical applications. All that can be expected from the best of them is some diminution of pain, and from the worst of them an increase of it, with a more rapid extension of the gangrenous mischief.

When the toes are to all appearance, perfectly mortified, and seem so loose as to be capable of being easily taken away, it is in general thought right to remove them. But however loose they may seem, if they be violently twisted off, or the parts by which they hang be divided, a very considerable degree of pain will most commonly attend such operation, which therefore had much better be avoided; for Mr. Pott has seen this very pain thus produced bring on fresh mischief, and that of the gangrenous kind. If the patient does well, these parts will certainly drop off; if he does not, no good can arise from removing them.

When the disorder is attended with a great deal of irritation, many subsequent practitioners have attested the efficacy of opium; though it has not always had the same success in their hands, when the mortification depended chiefly on constitutional debility. Dr. Kirkland observes, that we must be careful not to force the doses, especially at first; and that the medicine does more harm than good when its soporific effects go so far as to occasion delirium, take away the appetite, or cause affections of the heart. Sir A. Cooper joins opium with subcarbonate of ammonia, and in a case which I lately attended with him, he also prescribed musk, and wine and porter were allowed. As far as I could judge, the medicines which seemed to have the most effect in prolonging the patient's existence were opium, the sulphate of quinine, and castor oil, with other mild aperients.

Some authors recommend camphor. Pouteau attributes considerable efficacy to it when given in the dose of five grains, with a double quantity of nitre, every four hours.

Few surgeons of the present day believe that opium possesses as much power in the preceding cases as Mr. Pott represented. While Dr. Thomson allows that opium is much more entitled to the attention of practitioners than bark in the treatment of mortification, yet (he observes) "I would not by any means have you to place the same reliance on its powers for stopping even the mortification of the toes and feet in old people, which appears to have been done by Mr. Pott. From the trials which I have made, and which I have seen made by others, I cannot allow myself to believe that its powers in stopping this particular sort of mortification are greater than in stopping any other form or variety of the disease. It is obvious, however, from Mr. Pott's account, that his mind was strongly impressed with a very different opinion. His opinion seems to me to have been formed from the results of a very small number of cases, and in complete forgetfulness of the invaluable observations of his preceptor Mr. Sharp, with regard to the frequent spontaneous stoppage of mortification in cases in which no medicines whatever are used."—(See *Thomson's Lectures on Inflammation*, *p.* 568.)

I believe that this species of mortification very rarely attacks both feet. One remarkable instance of such an occurrence, however, I attended in the summer of 1828 with Mr. Hughes of Holborn; and the gentleman who was the subject of the disease was also visited by Sir Astley Cooper. Both feet and legs were attacked, and gradually destroyed nearly up to the knees. The patient lived a month after the commencement of the disorder. During most of this time the pulse was from 100 to 130; and the stomach so little disturbed, that the patient used generally to eat a mutton chop for dinner until the last two or three days preceding his death. Until the final stage, there was scarcely any delirium. Two circumstances were particularly noticed; first, that the disease never extended itself without being preceded by violent pains in the parts about to be destroyed, so that a judgment could always be formed beforehand from the degree of suffering, whether the spreading of the disorder would be considerable or not. Secondly, that the process of mortification, and its appearances in one leg, were totally different from those exhibited in the other. In the left, the disorder began on the inside of one of the toes, and followed the course described by Pott; in the right, a general diminution of the temperature of the foot and leg was the first thing noticed, without any discolouration of the skin, or any vesications or spot on the toes. The coldness, after increasing very much, was followed by total loss of sensibility in the parts, and the cessation of the circulation and every other action in them; the flesh being little more changed in its appearance than that of the limb of a dead subject.

2. With respect to the external or local treatment of mortification, the first indication consists in removing, if possible, such external causes as may have occasioned, or kept up the disorder; as the compression of bandages, ligatures, tumours, all irritating substances, &c.

When mortification arises from inflammation, which still prevails in a considerable degree, it is evident that the dead part itself only claims secondary consideration, and that the principal desideratum is to prevent the mortification from spreading to the living circumference, by lessening the inflammation present. Hence, under such circumstances, the application of linen wet with the saturnine lotion, and the maintenance of a continued evaporation, from the inflamed parts surrounding the mortified flesh, must be just as proper as if the mortification itself did not exist, and were quite out of all consideration.

It has been justly remarked by an eminent man (*Hunter*), that the local treatment of mortification (meaning that in consequence of inflammation) has been as absurd as the constitutional; scarifications have been made down to the living parts, in order that stimulating and antiseptic medicines might be applied to them; such as turpentines, the warmer balsams, and sometimes the essential oils. Warm fomentations have been also applied, as being congenial to life; but warmth always increases action, and should therefore be well adjusted to the case; while, on the other hand, cold debilitates or lessens powers, when carried too far, though it first lessens action. Stimulants are likewise improper, as the actions are already too violent. It is proper to keep the parts cool, and all the applications should be cold. In cases of mortification from inflammation, good effects have also been seen to arise from the topical as well as internal employment of opium.

But it must be acknowledged, that however proper the employment of cold applications may be in principle, in cases of mortification attended with inflammation, fomentations and emollient poultices are most commonly preferred in practice.

Besides common poultices, there are several others which have acquired great celebrity as topical applications in cases of mortification. Of this kind are the cataplasma carbonis,* cataplasma cerevisiæ,† and the cataplasma effervescens.‡ In nine cases out of ten, perhaps, they answer better than any others.

With respect to stimulating and spirituous applications, such as brandy, spirit of wine, balsams, resins, and aromatic substances, which have been recommended by a vast number of authors, they are nearly abandoned by modern practitioners. Though such things are indeed really useful in preserving dead animal substances from becoming putrid, a very little

* Prepared by mixing about ℥ ij. of finely powdered wood-charcoal with half a pound of the common linseed poultice.

† Prepared by stirring into the grounds of strong beer as much oatmeal as will make the mass of a suitable consistence.

‡ Prepared by stirring into an infusion of malt as much oatmeal as will render the substance of a proper thickness, and then adding about a spoonful of yeast.

knowledge of the animal economy is requisite to make us understand that they cannot act in this manner on parts still endued with vitality; but, on the contrary, that they must have highly prejudicial effects in the cases under consideration, by reason of the violent irritation which they always excite, when applied to the living fibres. It may indeed be justifiable now and then to apply spirituous applications to the dead parts themselves, with a view of diminishing the fetid effluvia, which, by contaminating the air, have some share in injuring the patient's health: but the greatest care is requisite to keep these stimulants from coming into contact with the living surfaces around and beneath the sloughs.

A few surgeons, however, still place confidence in stimulating applications. "In the less acute and more chronic cases of gangrenous inflammation, as in malignant erysipelas and carbuncle, in the gangrene of the toes and feet of old people, in the sphacelating state of hospital gangrene, and in severely contused wounds, in which gangrene and sphacelus have supervened, the emollient poultice, which is applied to promote the separation of the dead parts, may have an addition made to it of a greater or less quantity of the unguentum resinosum, or even of oil of turpentine itself. In the more severe of these cases, where we have reason to dread the extension of the sphacelus, warm dressings, as they have been termed, which are formed by dipping pledgets of charpie in a mixture of equal parts of the unguentum resinosum and oil of turpentine, may be applied, of a temperature as hot as the patient can bear without pain; and over these we may lay an emollient poultice, of a large size and soft consistence.

"After the sphacelus stops, and the process of ulceration begins in the inflamed line of contact, between the dead and living parts, it will often be found that the turpentine dressings are too stimulating, and occasion a considerable degree of pain. When this happens, we must either diminish the quantity of the turpentine in the dressings, or remove it altogether, according to circumstances. Besides the pain, a considerable extension of the ulceration would be, in general, the effect of continuing these applications after they begin to produce uneasiness. The ulcerating surface is, in the progress of separation, liable to pass, under every mode of treatment, into the state of a painful and irritable ulcer; and in this state it may require to be treated with decoctions of poppy heads, or with the application of the turnip, carrot, fresh hemlock leaf, stale beer, fermenting poultices, &c."—(See *Thomson's Lectures*, *p.* 577, 578.)

Hospital gangrene is undoubtedly a case that requires powerful applications, like Fowler's solution of arsenic, or the undiluted mineral acids; and, in Guy's Hospital, phagedenic sloughing ulcers are usually treated by Sir A. Cooper with the nitric acid lotion, 50 drops to a pint of water, and the internal exhibition of the subcarbonate of ammonia. He speaks also of a port wine poultice as an excellent application. The cases termed sloughing phagedena by Mr. Welbank, and considered by him as analogous to hospital gangrene, may be cured by dressing them with the undiluted nitric acid.—(See *Hospital Gangrene*.) I conceive that it has only been in hospital gangrene, and other cases of sloughing phagedenic ulcers, that various acids, diluted or undiluted, other caustic substances, and the actual cautery, have proved really serviceable. The muriatic acid, diluted with six times its quantity of water, was particularly recommended by Van Swieten, who applied it after making scarifications. In this manner, he stopped a sloughing disease extending all over the scrotum and penis. This author strongly recommends the same topical application to the gangrenous state of the gums in cases of scurvy. In this kind of case, he mixed the muriatic acid with honey, in various proportions; sometimes he even employed the pure acid itself for touching the parts which were likely to slough. It is also by supposing that the diseases referred to were of a phagedenic character, that I account for the good effects imputed by Dr. Kirkland and others, in cases of mortification, to another still more active caustic, namely, a solution of mercury in nitrous acid, with which the edges of the living flesh were touched. At all events, if the diseases were common cases of sloughing, I infer that such remedies were not really necessary, and that nature triumphed both over the disease and the supposed remedy. The following is a case related by Dr. Kirkland:

A man met with a fracture of the forearm, and the ends of the bones projected through the integuments. The fracture was very expeditiously reduced; but at the end of five or six days the whole arm seemed to be completely mortified up to the shoulder. Amputation was performed as near the joint as possible, and the stump, which had mortified as far as the acromion, was cauterized. The following day the mortification had reached the inferior extremity of the scapula. A little of the solution of mercury in nitrous acid was now applied by means of a probe along the edges of the parts affected, and from this moment the disorder made no farther progress. This cauterizing was repeated every day for seventeen or eighteen days. The sloughs and even the scapula itself were detached, and the patient got well.

On the continent liquid caustics are sometimes used as topical applications to gangrenous diseases, more especially, however, in cases of hospital gangrene and malignant carbuncle. Of this last disorder Larrey has recorded a very dangerous example, in which he effected a cure by first cutting away as much of the sloughs as possible, and then applying to the disorganized surface liquid caustics. Under the use of emollients two persons had already fallen victims to the disease in the same family.—(See *Mém. de Chir. Militaire*, *t.* 1, *p.* 53.)

With respect to the actual cautery, Celsus recommended it to be applied to the line which separates the dead parts from those which are still living, whenever medicines, and particularly topical emollient applications, failed in stopping the progress of the disorder. Pouteau ventured to revive this practice, which had been entirely exploded from modern surgery, and he was of opinion that the method would have the most beneficial effects in cases of erysipelatous gangrene, which is so often seen in hospitals in consequence of wounds. For this purpose he recommends cauterizing chiefly the edges of such parts as are of a dark red colour, and are on the point of perishing: and he advises this to be done with a heated iron or boiling oil, and to repeat the cauterizing of the dead parts at every time of dressing them, until the sensation of heat is even felt with a certain degree of force in the sound parts. The whole of the affected part is afterward to be covered with a large emollient poultice.

Pouteau relates a case of anthrax which took place on a woman's cheek, and which he cured in the above manner. The tumour, which on the third day was quite black, and as large as a walnut, was accompanied by an erysipelatous œdema, which extended over the whole cheek, eyelids, and front of the neck. Pouteau, after having opened the tumour in different directions with a lancet, introduced the red-hot cautery, and repeated the application several times, until the heat was felt by the sound flesh. The patient felt herself very much relieved immediately after this had been done; an oppressive headache, and a very afflicting sense of strangulation, which she had before experienced, were got rid of, and in ten days more the slough was detached on the occurrence of suppuration. —(*Encyclopédie Méthodique*, *Partie Chirurgicale*, *Art Gangrene*.)

But, perhaps, of all the species of mortification, hospital gangrene is that for which the use of caustics and the actual cautery itself has had the most numerous and respectable advocates. The heated iron is even now employed by the first surgeons of Paris for this particular case.—(See *Sketches of the Medical Schools of Paris*, *by J. Cross*, *p.* 84; and *Hospital Gangrene*.)

The foregoing observations are introduced into this work, that the reader may not be left entirely ignorant of what violent measures have been adopted in cases of mortification, and the account is not given in order that such practice may be again imitated, except perhaps in certain cases of phagedena and hospital gangrene, cases in which the most powerful local applications seem indispensable.—(See *Hospital Gangrene* and *Nitric Acid*.) The common employment of these terrible applications, viz. the actual cautery, the undiluted mineral acids and boiling oils, is as unscientific and unnecessarily painful as it is unproductive of any essential good. The grand object in almost every case of mortification is to diminish the irritation of the parts

in immediate contact with those already dead. This is indicated, lest the parts still alive and so situated should experience the same fate as the contiguous ones. In most of the other cases specified by Dr. Thomson, my experience leads me to prefer emollient soothing applications, none of which are stronger than the cataplasma carbonis, or the stale beer, fermenting, hemlock, or carrot poultices. When the process by which a slough is detached is somewhat advanced, I have seen a weak solution of the extract of opium in water put under the emollient poultice, along the line of separation, give considerable ease, at the same time that it seemed to promote the changes by which the dead parts were loosened.

In the gangrene produced by pressure and weakness, in persons who are compelled by diseases and injuries to lie for weeks and months in one posture, the mode of treatment is a matter of extreme importance, and frequently makes the difference of life or death to the poor sufferer. This affection usually has its seat in parts which are but thinly covered with muscular flesh. It occurs towards the latter stages of long-continued febrile diseases, as after typhus or hectic fever, attended with tedious suppurations; or even without these fevers, as in paralysis, and in very bad compound fractures. However, as Dr. Thomson observes, there are two forms of disease arising from pressure which have not always been accurately discriminated. One of these is the preceding sort of sloughing; the other is a chafed, excoriated, and ulcerated state of the parts.

Sometimes uncleanliness tends to cause this sort of mortification, that is, when the urine wets the patient's clothes. When this is the case, such irritation must be prevented by every possible means. If the skin be excoriated and broken, the powder of tutty, or lapis calaminaris, should be sprinkled over the part; or if an ointment be required, says Dr. Thomson, those which contain zinc or lead are the best. But when the ulceration threatens to extend, these remedies are to be laid aside, and an emollient, hemlock, carrot, or fermenting poultice used.—(*P.* 580.) I have seen, in the irritable state of such ulceration, the solution of opium under a common linseed poultice do more good than any other application.

Sir A. Cooper recommends the application of turpentine. Sometimes he uses a mixture of vinegar and camphorated spirit.

But no topical remedies will in any of these cases avail, unless the chief cause of the disorder be removed. This is to be effected by change of position, and laying pillows and cushions of the softest materials in convenient places under the patient; not directly under the disease itself, but in situations where they will tend to raise the parts affected from the contact of the bedding. A circular hollow pillow will often accomplish this important object; but when possible an entire change of posture is to be preferred.

When sphacelus succeeds to gangrene from pressure, I have often seen camphorated spirit applied; but never with decided advantage. A common emollient poultice, and in very bad cases the topical use of the solution of opium along the living margin, are the means upon which I place the most reliance, care being taken to improve the general health, without which grand indication neither the removal of the pressure nor the virtues of any dressings will answer. Dr. Thomson speaks most highly of the fermenting poultice, which I believe to be in these cases an excellent application. He confesses, however, that he has sometimes found it too stimulating, and been obliged to substitute the simple emollient, carrot, or turnip poultice.—(*P.* 580.)

When mortification arises from cold, every sort of warm emollient application must be avoided, and cold water, or even snow or ice, employed.—(See *Chilblains.*)

The local treatment of the mortification of the toes and feet, as described by Mr. Pott, has been already considered, and is that to which my observations incline me to give the preference.

The gangrenous affection of the pudenda, to which female children are liable, was successfully treated by Mr. K. Wood, by applying the liquor plumbi acet. dilutus in a tepid state, and bread poultices made with the same lotion. As soon as the ulcers became clean, they were dressed with the unguentum zinci.—(See *Med. Chir. Trans. vol.* 7.) Other cases which also ended well have been dressed with lint dipped in camphorated spirit, and covered with a poultice; or, at first, poultices made with the opium lotion, and after the separation of the sloughs the ulcer was dressed with port wine and decoction of bark in equal proportions. In some cases, however, mild stimuli proved injurious.—(*James on Inflammation, p.* 289.)

Deep scarifications in the integuments. The majority of authors who treat of mortification recommend this plan in all cases. They even advise the incisions to be made down to the sound parts, in order to facilitate the application of topical stimulants, and to favour the operation of the supposed antiseptic qualities of these dressings. But with the exception of cases in which the gangrenous parts lie under an aponeurosis, or others in which the integuments which have escaped destruction cover a mixture of matter and sloughy cellular substance, either in consequence of foregoing inflammation or any other cause, such as the extravasation of urine in the scrotum, all scarifications which penetrate as far as the living parts, are often productive of the most serious mischief instead of advantage. Such incisions cannot be practised without occasioning a great deal of pain, and producing inflammation, which often makes the mortification spread still farther. But as parts which are in a complete state of sphacelus are absolutely extraneous substances in regard to those which still retain their vitality, all such portion of them as is already loose should be removed. By lessening the size of the putrid mass the fetor is diminished, an outlet may sometimes be made for the escape of a great deal of putrid discharge, which being confined might have a bad effect on the neighbouring living parts; and the latter are enabled to free themselves more easily from the rest of the sloughs.

The too common practice of accelerating with a cutting instrument the separation of the mortified parts, previously to the completion of the process by which nature breaks the connexion between them and the living flesh, in general ought to be strongly reprobated, as causing unnecessary pain and irritation, and creating the risk of a renewal of the sloughing. As far as my experience goes, gangrenous phagedæna is the only instance in which it seems useful to remove the sloughs before they are loose, so as to let the topical applications extend their action without delay to the subjacent living surface.—(See *Hospital Gangrene.*) Pott's sentiments with respect to the danger and inutility of cutting the tendons and ligaments, in the mortification of the toes and feet, have been already stated.

If the surgeon prudently let nature work, without disturbing her, the separation of the mortified from the living parts will soon follow the establishment of inflammation and suppuration at the edges of the slough.

But when the whole thickness of a limb is affected with mortification, ought the surgeon to leave things to nature? or ought he to have recourse to amputation?

In general, the performance of amputation is indispensable; not that nature would not in many instances detach the sphacelated part, but because a great length of time would be required for the completion of the process, and a serviceable stump would rarely be left.

Another important question then arises, should the surgeon amputate while the mortification is in a spreading state? Or ought he to defer the operation until the line of separation begins to form between the dead and living parts?

In the mortification of the toes and foot, in old persons, Sir A. Cooper forbids amputation whether there be healthy granulations or not, and he declares that if the operation be done, mortification of the stump and the patient's death will certainly follow.

"Amputation (says a distinguished professor) was long regarded as one of the most effectual means which could be employed to prevent the extension of gangrene. This practice, however, has not received the sanction of experience; on the contrary, it has been generally found, wherever it has been practised, in either acute or chronic gangrene, to accelerate much the progress of the disease; and in this way to hasten the death of the patient. The parts which were divided in amputation, though at a distance from a spreading gangrene and from sphacelus, were found

speedily to assume the appearance of the affection for which the operation had been performed. *Till, therefore, the adhesive inflammation comes on, and a distinctly marked separation of the dead from the sound parts takes place, amputation is in few if in any cases of mortification admissible.* We never know previously to this where a gangrene or sphacelus is to stop, nor whether the powers of the constitution be sufficient to sustain the injury that the mortification has inflicted. Even when the adhesive inflammation comes on, it is in most cases best to allow some time to elapse before we operate, partly with a view to give time for the constitutional symptoms to abate; in other instances, to allow the patient's strength to be recruited by nourishment and cordials; and partly also with a view to learn whether the constitution of the patient be indeed capable of so great a fresh shock as that which amputation must necessarily occasion."—(See *Thomson's Lectures*, *p.* 582.)

According to Richter, there is never any certainty that we are amputating in living parts. Mortification rapidly ascends along the cellular substance surrounding the large blood-vessels, and is frequently much more extensive internally than external appearances would lead one to suppose. The adjacent surface, still apparently alive, is often so affected that it must inevitably slough, though at present it may not actually have sphacelated. The surgeon imagines that amputation is performed on living parts, but soon afterward discovers that he has been dividing those which are dead. The operation, he observes, can do no good, while the mortification is in a spreading state, and it may do considerable mischief. The disorder continues to extend, because its cause still operates, and this is not removable by amputation. If the operation be now injudiciously undertaken, the sphacelus invades the wound, and is the more certainly mortal, as the stance has been farther weakened by amputation and its consequences.

Many mortifications, especially those which arise from external causes, very often spontaneously stop and separate. But the place where this will happen can never be foreseen. By amputating in this circumstance we run the risk of disturbing nature in her salutary work, and rendering the disorder fatal.

The following are the only cases in which Richter allows that the use of the knife is justifiable and proper. There exists a species of sphacelus which rapidly occasions death before it is yet of great extent. Here, indeed, amputation might be really advisable; but the nature of the case is unfortunately never disclosed before the fatal catastrophe. Were it not for the operation, some external injuries would be inevitably followed by mortification. In such cases, early amputation is evidently proper; for the simple incision is attended with less danger than sphacelus. Sometimes, says Richter, a sphacelus spontaneously stops. This happens most frequently in cases which originate from an external cause, such as a violent contusion, burn, &c. But the occurrence is not restricted to this kind of case, nor is it invariably attendant on it. When there are no other occasional causes present, the mortification does not readily go beyond the limits of the contusion or violent burn; but the interference of surgery can hardly ever put a stop to its progress, before it has spread as far as the extent of the local injury.—(*Anfangsgründe der Wundarzneykunst*, *b.* 1, *kap.* 3.)

How different are the doctrines of Baron Larrey upon this subject from those entertained by Richter, and, indeed, the generality of eminent modern surgeons! "Writers on gangrene, or sphacelus of the extremities (says Larrey), indiscriminately recommend the amputation of a sphacelated limb never to be undertaken before the mortification is bounded or limited by a reddish circle, forming a true line of separation between the dead and living parts. This circumstance can only occur in a case of spontaneous gangrene from an internal cause; or if it happens, as is very unusual, in a case arising from a wound, its progress is different, and it would be exceedingly imprudent to wait for it. *The gangrene from external injuries almost always continues to spread; the infection becomes general; and the patient dies.*"—(*Mém. de Chir. Militaire*, *t.* 3, *p.* 142.) Respecting the want of foundation for this hypothesis of infection, I need here offer no remarks, having already expressed my opinion upon it in a foregoing page. On the other hand, Larrey asserts, that, in the dry or spontaneous gangrene, absorption takes place with more difficulty, and it is not uncommon to see the sphacelated parts separate from the living ones by the powers of nature alone, without the general functions being impaired. He argues that there is a manifest difference between what he terms the *traumatic* and the *spontaneous* gangrene, or, in other words, between the *humid* gangrene from an external cause, and the *dry* gangrene, which ordinarily proceeds from an internal cause.—(*P.* 148.)

In cases of mortification, arising from external injuries, Larrey maintains, that, "notwithstanding any thing that writers and practitioners may allege to the contrary, we should not hesitate about promptly performing amputation, as soon as the necessity for the operation is decidedly established. There is no reason to apprehend that the stump will be seized with gangrene, as in the spontaneous mortification, which has not ceased to spread, *because the traumatic gangrene, after having arisen from a local cause, is only propagated by absorption*, and a successive affection of the texture of parts by continuity of the vessels. Amputation, performed in a proper situation, stops the progress and fatal consequences of the disorder.

"Supposing then the lower half of the leg should be affected with sphacelus, in consequence of a gun-shot injury, attended with a violent contusion of the part, and a forcible concussion of the vessels, nerves, and ligaments, if the skin is elsewhere uninjured, the operation may be done in the place of election, without any fear of the stump becoming gangrenous, notwithstanding the cellular membrane of the upper part of the member may be already affected. But when the skin of the whole leg is struck with mortification, the operation must be done on the thigh and no time should be lost. The same practice is applicable to the upper extremities. We must be careful not to mistake a limb affected with stupor for one that is actually sphacelated. In the first case warmth, motion, and sensibility are still retained, although the skin may be blackish and the parts may be swollen. Besides, if there were any doubt, it would be proper to try at first tonic repellent applications, and cordial medicines, &c."—(See *Mém. de Chir. Militaire*, *t.* 3, *p.* 152, 153.)
